BY THE SAME AUTHOR

A COMPREHENSIVE TREATISE ON
INORGANIC AND THEORETICAL CHEMISTRY

In Sixteen Volumes. With Diagrams.

- Vol. I. H, O.
- Vol. II. F, Cl, Br, I, Li, Na, K, Rb, Cs.
- Vol. III. Cu, Ag, Au, Ca, Sr, Ba.
- Vol. IV. Ra and Ac Families, Be, Mg, Zn, Cd, Hg.
- Vol. V. B, Al, Ga, In, Tl, Sc, Ce, and Rare Earth Metals, C (Part I).
- Vol. VI. C (Part II), Si, Silicates.
- Vol. VII. Ti, Zr, Hf, Th, Ge, Sn, Pb, Inert Gases.
- Vol. VIII. N, P.
- Vol. IX. As, Sb, Bi, V, Cb, Ta.
- Vol. X. S, Se.
- Vol. XI. Te, Cr, Mo, W.
- Vol. XII. U, Mn, Ma, and Re, Fe (Part I).
- Vol. XIII. Fe (Part II).
- Vol. XIV. Fe (Part III), Co.
- Vol. XV. Ni, Ru, Rh, Pd, Os, Ir.
- Vol. XVI. Pt. and General Index, completing the work.

MELLOR'S MODERN INORGANIC CHEMISTRY.

Revised and Edited by G. D. PARKES, M.A., D.Phil., in
collaboration with J. W. MELLOR, D.Sc., F.R.S.
With numerous Illustrations.

CONTENTS

CHAPTER XXV

THE STRUCTURE OF MATTER

- § 1. The Unitary Theory of Matter (1); § 2. Spectrum Analysis (5); § 3. Evidence for the Unitary Theory from Spectrum Analysis (11); § 4. Electric Discharges in Attenuated Gases (24); § 5. Cathode and Lenard Rays (25); § 6. Röntgen or X-rays (31); § 7. The Photoelectric Effect (41); § 8. The Radiation Theory of Chemical Action (44); § 9. Positive or Canal Rays (47).

CHAPTER XXVI

RADIUM AND RADIOACTIVITY

- § 1. Becquerel Rays (53); § 2. Radium (59); § 3. The Occurrence of Radioactive Substances (64); § 4. The Properties of Becquerel's Rays (73); § 5. Analysis of the Radiations from Radium (80); § 6. The Properties of Radium (90); § 7. Radium Emanation—Niton (95); § 8. The Products of the Rapid Decay of Radium Emanation—Radium-A to Radium-C (105); § 9. The Products of the Slow Decay of Radium Emanation—Radium-D to Radium-F (112); § 10. The Progenitors of Radium (118); § 11. The Descendants of Uranium and Radium (126); § 12. Actinium and its Putative Parent (132); § 13. The Decay Products of Actinium (138); § 14. The Transmutation of the Elements—Alchemy (147).

CHAPTER XXVII

THE ARCHITECTURE OF THE ATOM

- § 1. The Mutability of the Elements; and the Disintegration of Atoms (155); § 2. The Creation and Annihilation of Matter (159); § 3. Thomson's Corpuscular or Electronic Hypothesis of Matter (163); § 4. Electronic Hypotheses of Chemical Combination and Valency (183).

CHAPTER XXVIII

BERYLLIUM OR GLUCINUM

- § 1. The Discovery and Occurrence of Beryllium or Glucinum (204); § 2. The Extraction of Beryllia (207); § 3. The Preparation and Properties of Beryllium (211); § 4. The Atomic Weight and Valency of Beryllium (218); § 5. Beryllium or Glucinum Oxide (221); § 6. Beryllium or Glucinum Hydroxides (224); § 7. Beryllium or Glucinum Fluoride (229); § 8. Beryllium or Glucinum Chloride (231); § 9. Beryllium or Glucinum Bromide (233); § 10. Beryllium or Glucinum Iodide (234); § 11. Beryllium or Glucinum Sulphide and Sulphates (235); § 12. Beryllium or Glucinum Carbonate (242); § 13. Beryllium or Glucinum Nitrate (244); § 14. Beryllium or Glucinum Phosphates (246).

CHAPTER XXIX

MAGNESIUM

- § 1. The History of Magnesium (249); § 2. The Occurrence of Magnesium (251); § 3. The Preparation of Magnesium (253); § 4. The Physical Properties of Magnesium (257); § 5. The Chemical Properties of Magnesium (265); § 6. Magnesium Oxides and Hydroxide (280); § 7. Magnesium Fluoride (296); § 8. Magnesium Chloride (298); § 9. Magnesium Bromide (312); § 10. Magnesium Iodide (316); § 11. Magnesium Sulphides (318); § 12. Magnesium Sulphates (321); § 13. The Complex and Double Salts of Magnesium Sulphate (335); § 14. Magnesium Carbonate (349); § 15. Hydrated Magnesium Carbonates (354); § 16. The Solubility of Magnesium Carbonate (358); § 17. The Basic Magnesium Carbonates—Magnesium Oxycarbonates (364); § 18. Complex or Double Salts with Magnesium Carbonate (367); § 19. Magnesium Nitrates (379); § 20. Magnesium Orthophosphates (382); § 21. Magnesium Hydrophosphates (390); § 22. Magnesium Pyrophosphates (393); § 23. Magnesium Metaphosphates (395).

CHAPTER XXX

ZINC AND CADMIUM

- § 1. The History of Zinc and Cadmium (398); § 2. The Occurrence of Zinc and Cadmium (405); § 3. The Extraction of Zinc (411); § 4. The Physical Properties of Zinc (425); § 5. The Physical Properties of Cadmium (454); § 6. The Chemical Properties of Zinc and Cadmium (472); § 7. The Atomic and Molecular Weights of Zinc and Cadmium (501); § 8. The Preparation of Zinc and Cadmium Oxides and Suboxides (504); § 9. The Properties of Zinc and Cadmium Oxides (510); § 10. The Hydroxides and Peroxides of Zinc and Cadmium (521); § 11. Zinc and Cadmium Fluorides (533); § 12. Zinc and Cadmium Chlorides (535); § 13. Zinc and Cadmium Bromides (564); § 14. Zinc and Cadmium Iodides (574); § 15. Zinc and Cadmium Sulphides (586); § 16. Zinc and Cadmium Sulphates (612); § 17. The Ammino- and Complex Salts of Zinc and Cadmium Sulphates (633); § 18. Zinc and Cadmium Carbonates (642); § 19. Zinc and Cadmium Nitrates (650); § 20. Zinc and Cadmium Phosphates (658); § 21. Alloys and Intermetallic Compounds of the Calcium and Zinc Families (665).

CHAPTER XXXI

MERCURY

- § 1. The History and Occurrence of Mercury (695); § 2. The Preparation and Extraction of Mercury (700); § 3. The Physical Properties of Mercury (711); § 4. The Chemical Properties of Mercury (752); § 5. The Atomic Weight and Valency of Mercury (766); § 6. Mercurous Oxide (768); § 7. Mercuric Oxide (771); § 8. Mercury Ammonium Compounds (784); § 9. Mercurous Fluoride (793); § 10. Mercuric Fluoride (794); § 11. Mercurous Chloride (796); § 12. Mercuric Chloride (816); § 13. Mercuric Oxychlorides—Basic Mercuric Chlorides (839); § 14. Mercuric Ammino-chlorides (844); § 15. Double and Complex Salts of Mercuric Chloride—The Chloromercuriates (848); § 16. Ammoniobasic and Aquo-ammonio-basic Salts of Mercuric Chloride (862); § 17. Hydroxylamine and Hydrazine Compounds of Mercuric Chloride (872); § 18. Mercurous Bromide (874); § 19. Mercuric Bromide (877); § 20. Mercuric Oxybromides. Basic Mercuric Bromides (884); § 21. Compounds of Mercury, Bromine, and Ammonia (885); § 22. Double and Complex Salts of Mercuric Bromide—The Bromomercuriates (891); § 23. Mercurous Iodide (895); § 24. Mercuric Iodide (901); § 25. Ammino-, Ammino-basic, and Aquo-ammino-basic Salts of Mercuric Iodide (921); § 26. Double and Complex Salts of Mercuric Iodide—The Iodomercuriates (925); § 27. The Sulphides of Mercury (942); § 28. Mercuric Chlorosulphide, Bromosulphide, and Iodosulphide (961); § 29. Mercurous Sulphate (964); § 30. Mercuric Sulphate (969); § 31. Ammoniacal, Hydrazine, and Hydroxylamine Mercuric Sulphates (977); § 32. The Mercury Carbonates (980); § 33. Arrested Reactions (983); § 34. Mercurous Nitrate (984); § 35. Mercuric Nitrate (991); § 36. Ammonium Mercuric Compounds (999); § 37. Mercury Phosphates (1002); § 38. Ammonium Amalgam (1005); § 39. Amalgams of the Alkali Metals (1010); § 40. Amalgams of Copper, Silver, and Gold (1022); § 41. The Amalgams of the Metals of the Alkaline Earths (1030); § 42. The Amalgams of Beryllium and Magnesium (1035); § 43. The Amalgams of Zinc and Cadmium (1037); § 44. The Magnesium-Zinc Family of Elements (1049).

ABBREVIATIONS

aq.	= aqueous
atm.	= atmospheric or atmosphere(s)
at. vol.	= atomic volume(s)
at. wt.	= atomic weight(s)
T° or °K	= absolute degrees of temperature
b.p.	= boiling point(s)
°	= centigrade degrees of temperature
coeff.	= coefficient
conc.	= concentrated or concentration
dil.	= dilute
eq.	= equivalent(s)
f.p.	= freezing point(s)
m.p.	= melting point(s)
mol(s)	= $\begin{cases} \text{gram-molecule(s)} \\ \text{gram-molecular} \end{cases}$
mol(s)	= $\begin{cases} \text{molecule(s)} \\ \text{molecular} \end{cases}$
mol. ht.	= molecular heat(s)
mol. vol.	= molecular volume(s)
mol. wt.	= molecular weight(s)
press.	= pressure(s)
sat.	= saturated
soln.	= solution(s)
sp. gr.	= specific gravity (gravities)
sp. ht.	= specific heat(s)
sp. vol.	= specific volume(s)
temp.	= temperature(s)
vap.	= vapour

In the cross references the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus 4, 31, 33 refers to § 33, chapter 31, volume 4.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of triangular diagrams for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, 49, 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

ABBREVIATIONS

triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle ternary mixture. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

FIG. 1.

FIG. 2.

FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER XXV

THE STRUCTURE OF MATTER

§ 1. The Unitary Theory of Matter

Simplicity is the seal of truth. Nature is wonderfully simple, and the characteristic mark of a childlike simplicity is stamped upon all that is true and noble in nature.—M. SENDIVOGIUS (1650).

Chemistry marches towards its goal and towards its perfection by dividing, subdividing, and subdividing still again.—A. L. LAVOISIER (1789).

The properties of the different elements result from differences of arrangement arising by the composition and recombination of ultimate homogeneous units.—H. SPENCER.

BELIEF in the simplicity of nature is not logic but faith pure and simple. It is one of those insidious and dangerous *tacit* assumptions which often creep into scientific theories. Tacit assumptions are dangerous because they are usually made unconsciously, so that they appear to be self-evident truths, and prevent our harbouring the shadow of a doubt of their insidious character. True enough, as H. Poincaré has said: "Every generalization supposes in a certain measure a belief in the simplicity of nature . . . every law is considered to be simple until the contrary has been proved," but faith in this dogma has sometimes led men astray. In consequence, hypotheses have frequently flourished in spite of experimental evidence to the contrary. It is not at all uncommon to find that a law which appears to be quite simple, when the methods of measurement are crude and approximate, becomes exceedingly complex when more accurate data are available. We have found this to be the case, for instance, with Boyle's law, Charles' law, etc. Another example will now be given.

There was a marked tendency among the earlier Greek philosophers to postulate one single kind of matter, a **protyle**—*πρώτη*, earlier than, or first; *ἕλη*, matter, or the stuff of which the things are made—or **primal element**. This *prima materia* or potential matter was supposed to consist of parts which when grouped in different ways produced the various kinds of matter considered by them to be elemental. The hypothesis is sometimes called the **unitary theory of matter**: **all the different forms of matter in the universe are derived from one and the same primordial element**. The unity of matter, said G. D. Hinrichs, is as real as the unity of force.

The philosopher Anaximenes regarded air as the primal element; Herakleitos, fire; Pherekides, earth; W. Prout, hydrogen; and modern chemical philosophers, electrons, and possibly æther. Thales of Miletus, who flourished in the sixth century B.C., considered that water was the first principle. Thales' doctrine had many supporters—J. B. van Helmont (1682), etc.—it lived for nearly twenty-five centuries; and it was demolished in 1770 when A. L. Lavoisier demonstrated that water cannot be changed into earth.

In 1815 and 1816, W. Prout believed that the at. wt. of the elements were exact multiples of the at. wt. of hydrogen, so that an atom of any element must weigh a certain number of times as much as an atom of hydrogen. He said:

If the views we have endeavoured to advance be correct, we may also consider the *πρώτη ἕλη* of the ancients to be realized in hydrogen, an opinion, by the way, not altogether new. If we actually consider this to be the case, and further consider the sp. gr. of bodies in their gaseous state to represent the number of volumes condensed into one; or, in other

words, the number of the absolute weight of a single volume of the first matter which they contain, which is extremely probable, multiples in weight must also indicate multiples in volume, and *vice versâ*; and the sp. gr. or absolute weights of all bodies in the gaseous state, must be multiples of the sp. gr. or absolute weight of the first matter, because all bodies in a gaseous state which unite with one another, unite with reference to their volume.

According to Prout's hypothesis, the elements are different aggregates of the atoms of primordial hydrogen; that is, the different elements are polymers of hydrogen; in consequence, within the limits of experimental error, the at. wt. of the different elements should be expressible by whole numbers when the at. wt. of hydrogen is unity.

Many writers attracted by its apparent simplicity gave unqualified support to Prout's hypothesis; but an impartial review of the facts, with very much more refined data than were available in Prout's day, led J. S. Stas to state: "I have arrived at the absolute conviction, the complete certainty, so far as is possible for a human being to attain to certainty in such matters, that the law of Prout is nothing but an illusion, a mere speculation definitely contradicted by experience." J. C. G. de Marignac added:

If Prout's law is not strictly confirmed by experiment, it nevertheless appears to express the relation between simple bodies with sufficient accuracy for the practical calculations of the chemist, and perhaps also the normal relationship which ought to exist among these weights, when allowance is made for some perturbing causes, the research for which should exercise the capacity and imagination of chemists. Should we not, for example, be quite in keeping with the fundamental principle of the law in admitting the hypothesis of the unity of matter, if we made the following supposition to which I attach no further importance than that of showing that we may be able to explain the discordance which exists between the experimental results and the direct consequences of the principle? May we not be able to suppose that the unknown cause (probably differing from the physical and chemical agents known to us), which has determined certain groupings of primordial matter so as to give birth to our simple chemical atoms, and to impress each of these groups with a special character and peculiar properties, has been able at the same time to exercise an influence upon the manner in which these groups of atoms obey the law of universal attraction, so that the weight of each of them is not exactly the sum of the weights of the constituent primordial atoms?

Many have tried to reconcile W. Prout's hypothesis with facts by changing the standard of reference to an imaginary primordial element with an at. wt. eq. to half an atom of hydrogen (J. C. G. de Marignac); then to a quarter of an atom (J. B. A. Dumas). However, having once begun to divide the hydrogen atom, there was no limit to the process of subdivision, and the hypothesis could then be made to fit any conceivable set of at. wts. This tinkering with W. Prout's hypothesis brought it, for a time, into disfavour.

The elements, as has been said, are substances which have never been resolved into simpler substances; it is not said that the elements will never be decomposed into a more primitive form (or forms) of matter. **The atom of an element can be defined as a substance whose parts are held together by a force superior to any which has yet been brought to bear upon it.** The elements have hitherto proved undecomposable, but it is quite conceivable that they are not absolutely undecomposable. Much circumstantial evidence has accumulated in recent years which makes it increasingly difficult to believe that Dalton's atoms are absolutely indivisible; and to deny that all the different elements have been formed from one homogeneous simple primal form of matter. The hypothesis appears in the Hellenic philosophies, and in those of the Neo-platonists. Albertus Magnus, in his *De generatione elementorum*, said that "the first matter was not generated but created out of nothing." Roger Bacon also said in his *De arte chymicæ* (Frankfurt, 1603):

There are four elements: fire, water, air, and earth; that is, the properties of their condition are four: heat, cold, dryness, and wetness. *Yle* (ἕλη, matter)—the true matter—contains not heat, not cold, not dryness, not wetness. The elements are made of *yle*, and each of the other elements is converted into the nature of the other element, and everything into anything else.

Raymund Lully wrote¹ similarly in his *De materia*. He said: The *prima materia* exists in *potentia* in particular forms in all substances. The idea can also be traced under various guises through writings of the alchemists down to the present time. G. D. Hinrichs has called the *prima materia* **pantogen** (1857); W. Crookes, **protyle** (1886); and J. L. G. Meinecke, **urstoff** (1817). It has been said that protyle "is matter generalized, stripped of its distinctions, the same from whatever source derived; it is matter in potency rather than in act; intangible; inaccessible to sense perception; and probably indifferent to the solicitations of gravity."

The idea that all the different forms of matter represent different stages in the growing complexity of one single elemental form of matter, has haunted the human mind from the earliest times, and the belief that "unity is the law of God," or that *simplex veri sigillum*, has proved so peculiarly fascinating that a remarkable number of speculations have been spun about this theme. These ingenious and subtle systems are admirable works of art, but they are outside the realm of science so long as the evidence on which they are founded remains intangible and vague. In recent years still another hypothesis is claimed to have been woven with circumstantial evidence which is rather more substantial than the incomprehensible fictions of the metaphysicians, for it can be examined and tested by comparison with gross material facts. It is supposed that the elements have been developed by the condensation of a primitive form of matter; and that the different elements, as W. Crookes expresses it, have been evolved by a kind of struggle for existence where elements, not in harmony with their environment, have either disappeared—*extinct elements*—or have never existed; where elements—*asteroidal elements*—have come into being and survived only on a limited scale, as is the case with the *scarcer elements*; and where other elements predominate because the surrounding conditions have been favourable to their formation and preservation, *e.g.* the *common elements*. This circumstantial evidence can now be outlined:

1. Why do so many atomic weights approximate to whole numbers?—

The International Table of Atomic Weights, 1922, contains 83 elements, and of these, 43 are integers within one-tenth of a unit. This fact has nothing to do with Prout's discarded hypothesis, but the numbers are facts which can hardly be due to chance, because the probability of this occurring is exceedingly small—something like one in 20,000 millions. Calculations have been made by J. W. Mallet,² and R. J. Strutt. The probability that the deviations of the first 27 elements of low at. wt. from whole numbers (oxygen 16), should be by chance as small as it is, was found by W. D. Harkins and E. D. Wilson to be one in 15,000,000. It is argued that the approximation of the at. wt. of so many elements to whole numbers cannot be reasonably attributed to a fortuitous coincidence; or, as R. J. Strutt puts it, "to use Laplace's mode of expression, we have stronger reasons for believing in the truth of some modification of Prout's law than in that of many historical events which are universally accepted as unquestionable." The possible isotopy of the elements—*vide infra*—has thrown a new light on this subject.

2. Why do so many groups of the elements exhibit family relationships?—

If the elements are totally distinct and independent of one another, it is exceedingly difficult to reconcile the regularities and analogies of the elements in different groups revealed by a study of the triad families, and of Mendeléeff's law, the main characteristic of which is *relationship*. In the triads of the halogen family, said M. Faraday,³ "we seem to have the dawning of a new light indicating the mutual convertibility of certain groups of elements, although under conditions which as yet are hidden from our scrutiny." These triads and the periodic law dimly foreshadow an identical origin or common parentage of families of elements. The possible isomerism of the chemical elements was discussed by J. F. W. Johnston, S. Brown, R. J. Kane, G. Wilson, etc. A study of the alkali metals, the metals of the alkaline earths, the halogens, etc., makes it highly probable that the different elements of one family, at least, have been formed by the conglomeration of monads or atomicules formed of the same primal matter so

as to build up ordinary atoms of different sizes or shapes, that is to say, evolution has progressed from homogeneity to heterogeneity. In other words, said C. R. A. Wright, the so-called elements are allotropic modifications of a primitive matter, and they differ from one another in the amount of latent energy they contain per unit mass. The idea is illustrated by the homologous series of carbon compounds. For instance,

	Ethene. C_2H_4	Propene. C_3H_6	Butene. C_4H_8	Pentene. C_5H_{10}	Hexene. C_6H_{12}
Mol. wt.	28	42	56	70	84

apparently by the polymerization of an increasing number of CH_2 groups. This series rises in a similar manner to nearly $C_{30}H_{60}$, with a regular increase of 14 in the mol. wt. J. W. Döbereiner's triads too have emphasized similar "constant" differences in the at. wt. of related elements. Hence, argued T. Carnelley, if a body we know to be compound can play the part of an element, there is some plausibility in the suggestion that the elements themselves are not absolutely simple.

3. Why are closely related elements so often associated together in nature ?—

Chemists have long been struck with the peculiar way certain elements occur in the half-mile crust of the earth. Although no disturbing agent has been recognized at work in nature whereby the different kinds of elements are sorted like to like, yet certain groups of elements nearly always occur in juxtaposition. These individual elements are not plentifully distributed, and they are not easy to separate from one another—*pares cum paribus facillime congregantur*. For example, cobalt is perhaps never quite free from nickel, and *vice versa*; silver is almost invariably associated with lead ores and with gold; cadmium with zinc ores; selenium with the sulphur of pyrites; the members of the two groups of the platinum elements; the rare earths; etc. These associations and co-mixings cannot be entirely due to chance, for these elements are neither plentifully distributed nor have they any marked chemical affinity for one another. Consequently, it has been suggested that the elements in question were formed from some common material under almost identical conditions, and where slight variations in the conditions led to the almost simultaneous formation of closely related elements. Environment has determined the path of the evolution of the elements.

Additional circumstantial evidence for the unitary theory has been obtained from (4) the grouping of the spectral lines; (5) the magnetic and electric perturbations of the spectral lines; (6) the phosphorescent spectra of the rare earths; (7) spectra of the stars and nebulae; (8) electric discharges in attenuated gases; (9) radioactivity; etc.

§ 2. Spectrum Analysis

If there ever was a flank movement on Nature by which she has been compelled to surrender a part of her secrets, it was the discovery of the spectroscope, which enables us to peer into the very heart of Nature.—R. C. KEDZIE.

Near the beginning of the seventeenth century J. Kepler ¹ mentioned the play of colours which occurs when a beam of sunlight is observed through a glass prism ; and nearly half a century later, Isaac Newton proved experimentally that a beam of sunlight is composed of light rays of various colours perfectly blended and ranging from red through orange, yellow, green, and blue to violet. This Newton did by passing the beam of sunlight through a glass prism, and projecting the beam on to a screen. The violet, green, and blue rays are more bent in passing through the prism than the yellow, orange, and red rays. The beam of light after passing through the prism appears on the screen as an unbroken band of colours, which is called a **continuous spectrum**. Isaac Newton's work has been discussed by R. A. Houstoun. Any beam of white light can be used in place of sunlight, for instance, the light from an incandescent solid such as the limelight, Welsbach's mantle, incandescent carbon, etc. Isaac Newton admitted the beam of light through a circular aperture, but W. H. Wollaston, admitting the light through a narrow slit, noticed that the beam of sunlight furnished a spectrum which is crossed by a large number of **dark lines**—some sharp and well defined, others more or less faint and nebulous. J. von Fraunhofer happened to look at W. H. Wollaston's spectrum of the sun through a small telescope, and saw "an infinite number of vertical lines, darker than the rest of the spectrum, and some of them appeared entirely black." He carefully mapped the relative position of some 576 of these dark lines, and accordingly they are now generally called **Fraunhofer's lines**.

It was soon found that incandescent vapours and gases furnish a **discontinuous or line spectrum**, that is, a spectrum composed of a few **bright lines** instead of a continuous band. The line spectra of some elements are comparatively simple, for they display but a few clear distinct coloured lines—*e.g.* sodium a yellow line ; thallium a green line ; indium a blue and an indigo-blue line. Other elements have complex spectra containing numerous lines of varying intensity—*e.g.* barium, strontium, iron. The spectra of some elements, though complex, are easily recognized by the prominence and position of certain lines—*e.g.* the dark red line of rubidium, the blue line of cæsium, etc. The cause of the dark lines was quite inexplicable. As E. L. Larkin expressed it, "the human mind was now groping in darkness in the presence of one of the chief mysteries of nature." J. von Fraunhofer died without knowing their cause.

In 1822, D. Brewster interposed coloured glasses between the source of light and the slit, and found that the entire spectrum disappeared except the rays having the same colour as the glass ; J. F. W. Herschel did the same with coloured liquids. In both cases, all waves of light were quenched except those transmitted by the medium. It was also found that the luminous lines in certain flames corresponded with the dark lines in the solar spectrum, and D. Brewster tried to use the spectrum in the analysis of simple and compound bodies. W. H. F. Talbot also said :

The orange ray may be the effect of strontian, as J. F. W. Herschel has found a ray of this colour in the flame of muriate of strontian. Were this opinion correct, a glance at the prismatic spectrum of a flame would be sufficient to show that it contained certain substances which could otherwise be discovered only by laborious chemical analysis.

It was provisionally assumed that J. von Fraunhofer's lines were due to the lack of certain shades of colour in the spectrum of sunlight. This plausible hypothesis was tested by L. Foucault in 1849. He arranged an experiment in which a ray of sunlight was directed by means of lenses on to the glowing gases between the poles of an arc light which alone gave a spectrum with two yellow lines very

prominent. The mixed light was passed through a prism. L. Foucault expected the lacuna in the solar spectrum corresponding with the yellow lines of the glowing gases in the arc light would be filled by the latter; and that the yellow portion of the solar spectrum would be continuous. To his astonishment, the dark lines of the solar spectrum corresponding with the yellow lines were more pronounced than before. Hence the preliminary hypothesis cannot be true. L. Foucault then suggested the hypothesis that "the incandescent gases in the arc light have the power of absorbing the yellow from sunlight, as well as of emitting yellow light. The increase in the darkness of these lines is due to this absorbing power being greater than the emissive power." L. Foucault focussed the light from an incandescent carbon—which by itself gives a continuous spectrum—on to the incandescent gases between the carbon poles. Instead of getting the continuous spectrum of the incandescent carbon with yellow lines enhanced by the spectrum of the gases between the carbon poles, L. Foucault obtained a spectrum with the dark lines in the yellow portion. This experiment supported his hypothesis, **the same kind of light which a gas gives out when heated will be arrested if the attempt be made to pass the light through the gas**; had L. Foucault known that the yellow lines were due to sodium he would have recognized the origin of Fraunhofer's lines. This interpretation was made by G. G. Stokes, 1852. In 1859, G. Kirchhoff definitely settled the question. He said:

I formed a solar spectrum by projection, and allowed the solar rays concerned, before they fell on the slit, to pass through a powerful salted flame. If the sunlight were sufficiently reduced, there appeared in the place of the two dark lines, *D*, two bright lines; if, on the other hand, its intensity surpassed a certain limit, the two dark lines, *D*, showed themselves in much greater distinctness than without the employment of the salted flame.

This discovery, said E. L. Larkin, is equal in importance to that of the law of gravitation, for the one may be said to weigh the universe, and the other to tell of what it is made. The subsequent history of spectrum analysis is but an illustration of the fact that when the right explanation of a phenomenon has been found, the facts seem to arrange themselves about the theory as naturally as the particles of a salt in a soln. aggregate about the enlarging nucleus of a crystal.

R. Bunsen and G. Kirchhoff subsequently proved that, under like conditions of temp. and press., **every element in the gaseous state has its own characteristic spectrum; and reciprocally, the presence of the vapour of an element can be inferred with certainty when the characteristic lines are present.** The spectrum of an element is so definite and characteristic that it has been proposed to use this fact as part of the definition of an element. The spectrum of an incandescent vapour of a mixture of elements contains all the lines characteristic of each element in the mixture, and consequently it is possible to recognize each and all of them by measuring the position of the bright lines and comparing the lines with those of known elements. This method of detecting elements is called **spectrum analysis**. R. Bunsen and G. Kirchhoff were able to prove that the dark Fraunhofer's lines are due to the rays of light from an incandescent solid passing through vapours of various elements. For the characteristic bright lines of, say, sodium are changed into dark lines when the white light from an incandescent solid is allowed to pass through the vapour of this element. Hence, since the bright lines of the spectrum of a vapour are changed into dark lines, and the dark parts of the spectrum are changed into bright colours by the continuous spectrum of white light, it seems as if the whole spectrum is reversed with respect to the illumination. Hence, G. Kirchhoff called it a **reversed spectrum**. It also follows that Fraunhofer's lines are due to the rays of light from an incandescent sun passing through the sun's atm., and consequently the vapours of the elements whose line spectra correspond with the dark lines of the solar spectrum must be present in the sun's atm., and consequently

The spectrum catches tokens from his light
Of elemental kinship with the earth.—C. A. LANE.

By the aid of spectrum analysis, therefore, it has been possible to deduce the presence of a large number of known elements—nearly 40—in the sun's atmosphere from the coincidence of the bright lines furnished by elements in the laboratory with the dark lines in the solar spectrum. The halogen elements, nitrogen, oxygen, gold, mercury, and a few other elements, have not been detected in the sun. The spectrum of an unknown element—helium—was observed in the solar spectrum some thirty years before the corresponding element was discovered in the earth. The light from the fixed stars furnishes results similar to those obtained with sunlight. The lines of hydrogen, helium, carbon, magnesium, calcium, and iron have been detected in nebulae; and hydrogen and hydrocarbons have been recognized in comets.

The light from incandescent solids furnishes a continuous spectrum, but the spectra of gases and vapours are discontinuous and furnish line spectra. The spectrum of an element can be excited by feeding it into a flame—*flame spectrum*; by passing it through an electric arc—*arc spectrum*—or through the electric spark discharge—*spark spectrum*; by the action of light of suitable frequency—*fluorescent emission spectrum*. The *lines* of the characteristic spectrum of an element obtained under low dispersion are usually resolved into a number of *components* with a high dispersion. If some of the components of a line are very close to and faint compared with the others, they are called *satellites* of the brighter components. With a still higher dispersion, a stage is reached at which no further components of a line can be observed. The distinction, however, is largely one of degree. The wave-length of a complex line is that which would be obtained with a dispersion too small to resolve it into its components. In addition to one or more characteristic *line spectra*, some elements also show a **band spectrum**. Compounds usually emit continuous or band spectra, or else the line spectra of the constituent elements. In a typical band spectrum, there are a number of bands each consisting of a large number of lines ranged together in close sequence. The lines are more closely crowded at one end, which is regarded as the *head* of the band, while the crowding gradually becomes less towards the other end or *tail* of the band. J. Plücker and W. Hittorf, and J. Salet assumed that different allotropic forms are involved in the different spectra furnished by a gas. H. von Helmholtz suggested that the line spectra are produced by atoms, band spectra by molecules. This idea was developed by E. Wiedemann, A. J. Angström and R. Thalen, A. Wüllner, F. Zöllner, etc. In general, band spectra are characteristic of compounds, not elements; and the bands in the spectrum of nitrogen are assumed to be produced by the nitrogen molecule, not its atom.

Isaac Newton favoured the assumption that "light consists of exceedingly minute particles shot out from a luminous body, and causing the sensation of light when impinging on the retina." Newton's corpuscular theory explained the reflection and refraction of light very well, but it left unexplained numerous other phenomena. In 1678, C. Huygens suggested the wave theory of light, and his ideas were subsequently developed by T. Young and A. Fresnel. J. C. Maxwell showed that both light and electromagnetic phenomena are produced by waves transmitted through the æther, which differ only in their wave-length. A similar parallelism exists between ultra-violet light and the X-rays.

The theory of the spectrum is based on the hypothesis that every ray of light is propagated by a kind of vibratory, undulatory, or wave-motion, which possesses energy. The medium which propagates light is the immaterial plenum called the unknown æther. The æther is therefore an hypothesis to assist in picturing a mechanism by which energy can be propagated through space, and it is assumed that light is propagated by the vibratory or wave-motion of the æther. The velocity of light approximates 200,000 miles or 3×10^{10} cm. per sec., while the molecules of a gas travel about a quarter of a mile or 4.5×10^4 cm. per sec. There are two ways of measuring wave-motion: (i) the *vibration frequency* represented by the number of vibrations per sec.; the vibration frequency may also refer to the number of vibrations per cm., and is usually symbolized by ν ; and (ii) the *wave-length* represented

by the distance from crest to crest or trough to trough of a vibration, and usually symbolized by λ . The greater the frequency the shorter the wave-length and conversely. If V be the velocity of light, 3×10^{10} cm. per sec., the frequency representing the number of vibrations per cm. is represented by $\nu = V/\lambda$; but this unit, though used in theoretical work, is too large, and it is common to employ $\nu = 1/\lambda$ in experimental work. The wave-length can be expressed in terms of μ , *i.e.* 0.001 mm., or $\mu\mu$, *i.e.* 0.001 μ or 0.000001 mm., or in ten-millionths of a metre, 10^{-10} m., *i.e.* 0.1 $\mu\mu$, the last are called Angström's units—symbolized \AA —*e.g.* 0.589 μ = 589 $\mu\mu$ = 5890 \AA . The spectral lines of the different elements are referred to a scale of wave-lengths, and usually expressed in Angström's units. J. von Fraunhofer designated the chief lines he noted in the solar spectrum by the letters *A, B, C, D, . . .*, and since some of these lines coincide with the characteristic lines of known elements, certain lines of certain elements are sometimes designated by Fraunhofer's letters—*e.g.* the *D*-line of sodium.

The differently coloured rays of light depend on differences in the rates of vibration, or vibration frequency. There is a specific rate of vibration for each colour. There are myriads of rays of different wave-length in a beam of white light. It is the function of the spectroscope to separate these waves, so that the different rays are sorted in the order of their vibration frequency or wave-length. In the spectrum, the rays which produce the sensation of red are slowest, the violet fastest. When the eye receives nearly 400 billion of these vibrations per sec., it is agreed that the colour sensation is red; and if nearly 750 billion per sec., violet. All the different colours of the spectrum lie between these extremes. Otherwise expressed, the eye recognizes as light only those vibrations of the æther ranging between a wave-length 81 millionths of a cm. at the red end and 36 millionths of a cm. at the violet end. Some people's eyes are tuned to see a little further than others into the ultra-violet or the ultra-red.

In 1800, J. F. W. Herschel discovered the existence of the so-called **ultra-red rays** or the invisible heat rays in the region beyond the red in the visible spectrum; and the following year, J. W. Ritter discovered the so-called **ultra-violet rays** in the region beyond the violet of the visible spectrum. Two hypotheses were then invented: One assumed that there are three distinct types of rays present in light—the heating, the visible, and the actinic. It was further supposed that these rays overlapped somewhat in refrangibility, and thus the heating rays appeared in the red and orange, and the actinic in the violet and blue. The other hypothesis supposed all the rays to be the same in nature, *viz.* undulations in the æther; but the ultra-red and ultra-violet rays were supposed to differ somewhat in quality or intensity which made them invisible. Thus, the undulatory theory is monistic. It was championed by J. B. Biot in 1814 and by A. M. Ampère in 1832. The wave-length of the rays at the violet end of the spectrum is 4×10^{-5} cm., and at the red end, 7.5×10^{-5} . The wave-length of the ultra-red rays have been measured to 3×10^5 cm.—these waves correspond with the æthereal vibrations of the electromagnetic waves used in wireless telegraphy; and J. Schumann measured the wave-length of ultra-violet rays to 1.22×10^{-5} cm., or 1200 \AA , *Schumann's waves*, T. Lyman down to 0.51×10^{-5} , or 510 \AA , and R. A. Millikan and co-workers down to 0.32×10^{-5} cm., or 320 \AA . The X-rays have a wave-length between 10^{-8} and 10^{-9} cm. The visible spectrum thus represents a very limited region in the range of known æthereal vibrations, which progressively increase from 10^{-5} to 3×10^5 cm., and differ only with regard to the detectors employed to determine their presence. The term light is therefore extended, and it does not necessarily mean only visible light.

The rays at the red end of the spectrum produce thermal effects, and the energy of these heat rays has been explored in different parts of the spectrum and extended into the ultra-red. The rays at the violet end of the spectrum are the most active chemically, and these actinic rays extend well into the ultra-violet. The light at the red end of the spectrum are the least active chemically. These facts are utilized by the photographer, who employs ruby-glass or red screens to

cover the windows and lamps used for the dark-room. The ultra-violet rays are largely absorbed by glass, though quartz is fairly transparent to these rays. In illustration of the chemical activity of these rays, they decompose silver salts; the iodides of potassium, sodium, calcium, barium, zinc, etc.; ferric sulphate, nitrate, or chloride is reduced to the ferrous salt particularly in the presence of organic matter—e.g. cane sugar; soln. of chlorates and bromates are quite stable if exposed to sunlight in glass bottles, but they are appreciably reduced by light if kept in quartz vessels. The rate of reduction is augmented if sugar is present. Ultra-violet light decomposes ammonia, nitric and nitrous oxides, and carbon dioxide; it induces the combination of oxygen with hydrogen or carbon monoxide; and produces with oxygen, ozone; ultra-violet light ionizes air and other gases, and it produces the so-called photoelectric effect.

It might be added that the spectrum of a gas depends partly on the *temperature* and partly on the *pressure* under which the gas is confined. In passing to a higher temp., new lines are often added to a spectrum, and old lines disappear; for instance, the lithium spectrum in the electric arc shows a blue line not visible in the spectrum obtained by Bunsen's flame. The character of the lines also depends upon the temp. under which the gas or vapour is examined. Sodium in a Bunsen's flame, for instance, gives one well-defined yellow line which is really compounded of two yellow lines; but at higher temp. three other pairs of lines make their appearance. The difference between the high and low temp. spectra is sometimes so marked that in the early days of spectroscopy J. Plücker and W. Hittorf wrote: "There is a certain number of elementary substances which when differently treated furnishes two kinds of spectra of quite different character, not having any line or band in common." The variations in the spectra are characteristic, and *it is possible to deduce the approximate temperature from the corresponding spectrum of a substance.* In a general way, it may be said that the spectra of elements become more complex as the temp. is raised. In the case of compounds, too, A. Mitscherlich showed that they may have a characteristic spectrum in which no lines of the constituent elements can be detected; but if the temp. be high enough to decompose the compound, the characteristic lines of the constituent elements will appear. The spectra of some elements are influenced by the *medium*, so much so that the spectra may be obliterated or suppressed. The subject has been studied by G. E. Gibson and A. A. Noyes, etc.

At small pressures, spectra with broad bands are obtained. As the press. is increased, "new series of lines arise which existed only in germ at lower pressures"; the bands give way to lines, and finally a continuous band of light is obtained corresponding with the pure spectrum. Under great press., all incandescent solids, liquids, and gases emit continuous spectra. A. Wüllner, A. Schuster, G. Ciamician, G. D. Liveing and J. Dewar, etc., studied the widening of the spectral lines by press. E. Frankland and J. N. Lockyer found that if the press. of hydrogen be increased while an electric current is passing through the gas, the lines begin to expand until the spectrum becomes continuous, and finally, the resistance becomes so great that a current will not pass. J. P. Gassiot, and J. Plücker also found that if the press. of hydrogen be diminished, the electrical resistance attains a minimum; then increases, and finally becomes so great that a current will not pass. Hence, added A. Schuster, the resistance of the gas may be assumed to be the same when the current just ceases to pass, whether the increased resistance is produced by too great or too low a press. In the former case the gas is not heated so much as in the latter case, and yet the spectrum is not continuous nor are the lines widened. Hence, the observed widening of the lines, observed by E. Frankland and J. N. Lockyer, is not caused by a rise of temp. but by press. The widening in the spectra of some substances begins with the more refrangible lines, and in that of others, with the less refrangible lines. Thus, J. Plücker and W. Hittorf found the widening with hydrogen begins with the more refrangible lines; G. Ciamician found mercury behaved similarly. With oxygen, J. Plücker and W. Hittorf found the widening begins with the less refrangible

lines, and with sodium, and rubidium, J. N. Lockyer observed similar results. J. N. Lockyer found the 4210-silver line widened on the more refrangible side, and the 4054·3-silver line on the less refrangible side. T. R. Merton has discussed the subject. J. S. Ames, W. J. Humphreys and J. F. Mohler found that the press. does not act in the same way on the rays of different series of spectral lines, but for a given series they represent the effect of a change of press., dp , on the wave-length, λ , by $d\lambda = \lambda\beta.dp$, where β is constant for a given series. R. S. Hutton and J. E. Petavel studied the effect of press. up to 100 atm. on arc spectra.

Some substances absorb certain colours and transmit others; they may absorb light in lines as narrow and sharp as the lines in the emission spectrum. They were observed in the case of sodium vapour whose absorption spectrum appears as a dark line in the continuous background. The lines in the absorption and continuous spectra are not necessarily the same. Hydrogen, for instance, under normal conditions does not absorb any of the characteristic lines of its emission spectrum. If a coloured soln. be illuminated by the light from an incandescent solid transmitted through the soln., a series of dark bands or lines, called the absorption spectrum, is obtained. A number of soln. have very characteristic absorption spectra—e.g. blood, didymium chloride, copper sulphate, potassium chromate, potassium permanganate, potassium dichromate, etc. H. C. Jones and co-workers measured the absorption spectra of a number of soln., and inferred that the solute forms compounds with the solvent. They say that there is a gradual shift in the absorption band as one salt is transformed into another by the replacement of the acid radicle owing to the formation of intermediate compounds. T. R. Merton, however, showed that this statement is a mal-inference, and is readily explained by the superposition of two absorption curves; he also observed that press. up to 750 atm. had no influence on the absorption spectra of soln.

§ 3. Evidence for the Unitary Theory from Spectrum Analysis

The final impression our mind receives on contemplating these fundamental relations is that of a wonderful mechanism of nature, the functions of which are performed with never-failing certainty, though the mind can only follow them with difficulty, and with a humiliating sense of the incompleteness of its perception.—J. J. BALMER.

To produce light something must vibrate. It is assumed that the seat of the impulses which set up wave-motion in the æther are vibrating molecules, atoms, or maybe sub-atoms. It is assumed that each particular band or line is an effect of the periodic vibrations of particles, and that the line spectra are produced by vibrations confined to atoms, or parts of atoms, while with band spectra the vibrations are similarly confined to the molecules. Owing to the fact that each gas, when heated, has its own characteristic spectrum, it is inferred (i) that the rates of vibration of the particles of the hot gas which give rise to the spectrum are constant and characteristic; and (ii) that the vibrating particles of the gas set up corresponding vibrations in the æther which are recognized as light rays with a specific spectrum. The fact that the same kind of light emitted by a hot gas is arrested when the attempt is made to send that light through the gas, is taken to mean that when the rate of vibration of any ray of light coincides with the rate of vibration of the particles of the gas, the light will be more or less completely quenched by those particles because the energy of the light ray will be expended in setting those particles into vibration. W. C. D. and C. D. Whetham¹ express the idea of sympathetic vibrations neatly:

A child's swing is set in motion by giving it a series of small impulses which coincide with its natural period of oscillation, and in a similar manner any mechanical system will absorb energy which falls on it in rhythmic unison with its own natural vibrations.

Conversely, if a gas be heated sufficiently to set the particles vibrating vigorously enough to give out light, then the light will have the same colour as that which the gas could stop. The particles will act as storm centres and send out waves into the æther which appear as light. The absorption of different coloured rays by different gases thus indicate that the particles of a gas possess specific rates of vibration. The compression of a gas does not effect the rates of vibration of the particles or of the colours absorbed by the gas because the same coloured rays are absorbed by the compressed gas as were absorbed by the gas under ordinary press. Hence, the vibration is not a property of the gas as a whole—for the properties of a mass of gas are altered by compression—but it is a property of the separate parts of a gas which are only brought closer by compression while their rates of vibration are not affected. G. Ribaud studied the kinetic theory of the absorption of energy by the molecules of a gas.

The constancy of the spectral lines in the spectrum of a gas shows that the motions of the vibrating particles must be remarkably regular. The period of vibration of the particles, as revealed by the spectroscope, conditions a chemical property which, in the opinion of R. Bunsen, is as constant and fundamental as the at. wt. of the element, and which may be determined with very great exactitude; indeed, in 1900, the International Congress in Paris accepted a proposal by A. de Gramont that **no new substance be recognized as an element until its spark spectrum has been measured, and shown to be different from that of every other known form of matter.** The large number of spectral lines in the spectra of many elements, e.g. iron, shows that the vibrations which give rise to the spectrum must be remarkably complex. According to J. N. Lockyer, the lines are connected with the different vibratory powers of different portions of an atom. In other words, an atom is a

complex aggregate of particles, and hence H. A. Rowland was led to say that a grand piano must be a simple mechanism in comparison with a vibrating atom. All this is supposed to imply that the spectral lines are due to the vibrations of particles smaller than the atom, and that **the atom itself is a complex system made up of vibrating corpuscles**. Indeed, *the atom itself is now considered to be a kind of miniature planetary system embracing numbers of corpuscles each spinning in its own tiny orbit*. This recalls the speculation, where the individual atoms were supposed to whirl rhythmically in minute orbits to form molecules, much as the planets in the solar system revolve about the sun. The idea is quite an old one. S. Brown, for example, in 1843, said :

The atom is by no means essentially or even potentially indivisible. There is a possibility and likelihood that within the atom is another nameless world of the universe. Under the sky of the atom proceed worlds of material existence as different from atoms as atoms from compound particles ; as compound particles from crystal shapes ; as crystal shapes from stars and planets ; as stars and planets from solar systems ; or as solar systems from firmaments.

It will be observed that at least three characteristic spectra of an element may be possible, for the spectrum may be produced by the oscillations (i) of the molecule as one unit ; (ii) by the atom as one unit ; and (iii) by the sub-atoms, or parts of the atom. The recognition of the fact that the spectrum of an element depends on the structure of its molecules or atoms, induced hopes that a study of spectra would teach something about the structure of matter. The problem appeared to be immensely complex. Thus, R. W. Wood said :

The study of the structure of the molecule by means of the spectroscope might be likened to the attempt on the part of an individual who had no experience with or conception of any musical instrument to get a clear idea of all the musical instruments of an orchestra by listening to a concert.

The acoustical analogy encouraged investigators to seek for simple harmonic relations between the frequencies of the molecular vibrations, such as the whole-number ratios known to exist between the fundamental note and the overtones of an organ-pipe or piano-string. Thus, E. Mascart, L. de Boisbaudran, J. L. Soret, G. J. Stoney, G. D. Liveing and J. Dewar joined in the quest. At first glance, the spectral lines of a given element seem to be so complex that any attempt to reduce them to order appears to be hopeless. According to F. Exner and E. Haschek, the arc spectrum of uranium contains 4940 lines, and the spark spectrum 5655 lines. H. Kayser and C. Runge tabulated 4500 lines in the spectrum of iron. As a rule, the spectra of elements with large at. wt. are more complex than those of elements with low at. wt. G. J. Stoney noticed a semblance of order in the spectrum of hydrogen ; and A. Schuster asked : Is the number of whole-number ratios between the wave-lengths greater than would exist if the lines were distributed at random ? After examining the spectra of sodium, copper, barium, magnesium, and particularly iron, he concluded that the whole-number ratios were less than would be expected on a chance distribution. J. J. Balmer found that the wave-lengths of most of the hydrogen lines can be computed if whole numbers be substituted for m in a formula of the type $3647 \cdot 2m^2/(m^2 - 4)$, *vide* hydrogen, 1. 7, 7. The numerical relations between the lines of a spectrum are more readily discerned when the frequencies, ν , are substituted for the wave-lengths, λ , as indicated above, where $\nu = \lambda^{-1}$. In the search for analogous laws in the spectra of other elements, it was found that the lines of many apparently chaotic spectra can be resolved into a number of regular series superposed one on the other. Thus, **the spectral lines of the elements can be arranged in groups or series**. The spectrum of helium, for example, can be resolved into eight such series, each of which has lines which show a regular decrease in intensity with vibration frequency. Oxygen has a spectrum with six superposed sets of lines ; hydrogen and the alkali metals have each four such series. The metals in question have monatomic molecules, and hence it inevitably follows that the atoms

have a complex constitution, and that **the spectral lines are not all produced by the vibrations of the same kind of particles ; atoms are complex aggregates of vibration corpuscles.**

L. de Boisbaudran emphasized the similarities in the spectra of related elements. Some of these relations have been applied to estimate the at. wt. of the elements—*vide* gallium, and radium. He said :

In the natural families of elements, the variation in the increment of the at. wt. is proportional to the variation in the increment of the wave-length of homologous rays or groups of rays in the third harmonic of the spectrum.

Although the spectrum of each element is characteristic of that element and of no other, yet the spectrum of each of the five alkali metals can be resolved into four homologous series such that every line in one spectrum is represented by a corresponding line on all the other spectra ; and generally, **the spectra of related elements form natural or homologous groups.** The corresponding lines do not necessarily all occur in the visible spectra, *e.g.* the dark red line of the rubidium spectrum corresponds with a line in the ultra-red in the other spectra ; and the yellow lines of the sodium spectrum are homologous with lines in the ultra-violet spectra of the other elements. The spectra of related elements seem to be subject to a law of homology which is closely connected with their at. wt. Each series of homologous lines appears to contract in passing from one element to another so that as the at. wt. increases, the lines at the red end of the spectrum appear to open further apart, and at the violet end, to draw closer together. Thus, C. Runge represented the spectral lines of the alkali metals by dots, Fig. 1, so that their limits at the violet end coincide ; it will be seen that the lines of this particular series contract in passing from lithium to caesium, and the relation between the contractions and the at. wt. of the elements is shown in the diagram by making the distances between the lines represent the magnitude of their at. wt.—*vide* 2, 20, 7. Similar remarks apply to the spectra of many other families of elements.

FIG. 1.—One Series of Homologous Spectra of the Alkali Metals Spaced according to their Atomic Weight.

According to D. I. Mendeléeff, the chemical and physical properties with the odd or even series of elements in the periodic table, resemble one another more closely than they do with elements immediately adjoining. Thus, the spectra of gallium, indium, and thallium in the third odd series resemble more the spectra of their homologous potassium, rubidium, and caesium in the first series, than the spectra of their homologous calcium, strontium, and barium in the second even series. In a given natural group, C. Runge found that with increasing at. wt. in chemically related series, *i.e.* the vertical series of the periodic table, the spectral lines shift towards the less refrangible or red end ; while the spectra of elements in a horizontal series—*e.g.* like sodium and magnesium, potassium and calcium, etc.—shift in the opposite direction, so that the spectrum of an element with the greater at. wt. is as a whole situated nearer the more refrangible or violet end. The difference, ν , in the vibration frequency of a doublet in the spectra of the elements in a given family is proportional to the squares of the at. wt., A , and the values of νA^{-2} lie on a straight line, as illustrated by Fig. 2. The values of lithium, sodium, and aluminium deviate from the straight line belonging to the members of their respective families. Many of the relations between the properties of the elements and the at. wt. also apply to the at. numbers.

There is thus a family likeness between the spectra of related elements, and a close connection has been traced between the at. wt. and the differences in the vibration frequencies of the lines in the members of a given family of elements. The at. wt. of groups of related elements with their related physical and chemical properties differ by definite values, and the spectra of these elements show that

which can be simplified until it resembles the second of formulæ (4). E. E. Mogendorff (1905) and W. M. Hicks (1910) used the formula

$$\nu = A - \frac{N}{(m + a + bm^{-1})^2}$$

where A , a , and b are constants. Assuming that $\nu = (m, a)$ represents equation (3), a typical spectrum in which there are four groups of series with $a = s, p, d$, and b , where m in the s -group may have any value from unity upwards; in the p -group, any value from 2 upwards; in the d -group, any value from 3 upwards; and in the b -group any value from 4 upwards. Then, the different series of lines are:

PRINCIPAL SERIES.				SUBSIDIARY SERIES.			
First	.	.	.	$\nu = (1, s) - (m, p)$	First or diffuse	.	$\nu = (2, p) - (m, d)$
Diffuse	.	.	.	$\nu = (1, s) - (m, d)$	Second or sharp	.	$\nu = (2, p) - (m, s)$
Sharp	.	.	.	$\nu = (1, s) - (m, s)$	Third	.	$\nu = (2, p) - (m, p)$
Bergmann's series				.	$\nu = (3, d) - (m, b)$		

where the m in the second term is greater by one than the constant number in the first. The principal series always contains the most intense characteristic lines of the elements. F. A. Saunders, A. del Campo and M. A. Catalan, A. Kratzer, O. Oldenberg, P. D. Foote and F. H. Mohler, and A. Fowler have also discussed series spectra.

When a solid is heated to a high enough temp., light is emitted; and this light can be resolved into a continuous spectrum. The distribution of the energy for light of different wave-lengths can be measured by a bolometer. In general, the relation between the intensity of the radiant energy and the wave-length depends on the nature and temp. of the heated body. A uniformly heated enclosure, which absorbs completely all the radiation falling upon it, is a perfect radiator of heat; and the thermal radiation which it emits is a function of temp. only, and is independent of the nature of the material. A substance possessing such properties is called a *black body*. No known substance is a perfect black body—lamp-black is a close approximation; platinum and white oxides depart considerably from black-body radiation. The relation between the temp. T , and the energy of black-body radiation, E , established by J. Stefan, L. Boltzmann,² and O. Lummer and E. Pringsheim, is $E = 5.6 \times 10^{-5} (T^4 - T_0^4)$ ergs per sq. cm. per sec. This is known as the **Stefan-Boltzmann radiation law**. Here T denotes the absolute temp. of the radiating body, and T_0 the temp. of the body receiving the radiations.

Lord Rayleigh found the relation between the radiant energy, E ; the wave-length, λ , or the vibration frequency, ν ; and the absolute temp., T , is

$$E = \frac{V k T}{\lambda^4}; \quad E = \frac{\nu^2}{V^2} k T$$

where V denotes the velocity of light, 3×10^{10} cm. per sec.; and k is the so-called gas constant per atom or 1.37×10^{-16} ergs per degree. W. Wien gave

$$E = V^2 h \lambda^{-5} e^{-\frac{V h}{k T}}; \quad E = h \nu^3 V^{-2} e^{-\frac{h \nu}{k T}}$$

where h is the universal gas constant, 6.62×10^{-27} erg-sec. M. Planck gave

$$E = \frac{V^2 h \lambda^{-5}}{e^{\frac{V h}{k \lambda T}} - 1}; \quad E = \frac{h \nu^3 V^{-2}}{e^{\frac{h \nu}{k T}} - 1}$$

W. Wien's equation fits low values of λT ; Lord Rayleigh's high values; and M. Planck's is applicable over the whole range.

M. Planck's radiation formula is alone based on the quantum theory of energy—2. 13, 15. The formulæ of Lord Rayleigh, and W. Wien are based on electrodynamics, and thermodynamics and the equipartition of energy—2. 13, 10. M. Planck assumes (i) that there exists in the enclosure linear oscillators similar to those used in the production of Hertzian waves but of molecular dimensions, so that the frequencies of the harmonic vibrations emitted by them are of the order of magnitude of those present in the radiation from the black body; (ii) that an oscillator cannot take up energy continuously, but *discontinuously in multiples of a unit*

quantum ϵ ; and (iii) that the unit quantum which the oscillator can emit or absorb is proportional to its frequency, ν ; that is, $\epsilon=h\nu$, where h is a universal constant. He added:

In what way we are to conceive the nature of quanta of a purely dynamical nature, we cannot yet say for certain. Possibly such quanta might be accounted for if each source of radiation can emit energy only when that energy attains at least a certain minimum value; just as a rubber pipe, into which air is gradually compressed, bursts and scatters its contents only when the elastic energy in it attains a certain value. In any case, the hypothesis of quanta has led to the idea that there are changes in nature which do not occur continuously but in an explosive manner. I need hardly remind you that this view has become much more conceivable since the discovery and investigation of radioactive phenomena. Besides, all difficulties connected with detailed explanation are at present overshadowed by the circumstance that the quantum hypothesis has yielded results which are in closer agreement with radiation-measurements than are all previous theories.

According to the quantum theory of energy (1. 13, 15), if h is the universal constant or 6.62×10^{-27} in erg-sec. units; ν the vibration frequency of the radiation; and W the radiant energy; then $W=h\nu$, or $nW=n h\nu$, where n is an integer usually unity. This expression means that radiant energy of frequency ν is always radiated in bundles or quanta. The yellow sodium D -line has a wave-length 0.5896μ , so that the vibration frequency is $\nu=3 \times 10^{10} \div 0.5896 \times 10^{-4}=5.088 \times 10^{14}$; and $h\nu=6.62 \times 10^{-27} \times 5.088 \times 10^{14}=33.69 \times 10^{-13}$ ergs. Hence, remembering that a watt is 10^7 ergs per sec., it follows that the energy quanta involved are very small. If the conservation of energy is applicable, then in passing from a state a to a state b , the atom parts with energy W_a-W_b . It is shown that atoms may occur in (i) a normal or electrically neutral state, and (ii) the charged or ionized condition. If each of these states has a characteristic spectra, and all other states are intermediate between these two, then the work required to make the atom pass from the state a to the state b is equal to the work of ionizing the atom. The terms of the spectrum of an element converge to zero frequency at one end, and cease at a frequency ν_a at the other end, the extreme difference of frequency is ν_a , so that the extreme difference of energy should be $h\nu_a$, and this should represent the work, W_0 , required to ionize the atom, or $W_0=h\nu_a$. The **ionizing potentials** of some metal vapours are shown in Table I, and the results are well in accord with the hypothesis. h is here expressed with the volt as unit of energy and 3×10^{-10} sec. as the unit of time. To express h in ergs multiply the tabulated values by 5.30×10^{-23} . This

TABLE I.—IONIZING POTENTIALS OF VAPOURS.

	Ionizing potential W_0 volts.	Frequency ν_a per cm.	Ratio $W_0/\nu_a=h$.
Mercury . . .	10.38	6.17×10^4	1.257×10^{-4}
Cadmium . . .	8.9	7.25×10^4	1.23×10^{-4}
Zinc	9.5	7.58×10^4	1.25×10^{-4}
Cæsium . . .	3.9	3.14×10^4	1.24×10^{-4}
Rubidium . .	4.1	3.37×10^4	1.22×10^{-4}
Potassium . .	4.1	3.50×10^4	1.17×10^{-4}
Sodium . . .	5.13	4.14×10^4	1.238×10^{-4}

gives a mean value 6.52×10^{-27} . J. H. Jeans, C. F. Bickerdike, etc., have discussed the relation between radiation and the emission of electrons; K. T. Compton has discussed the ionization of gases at potentials below the so-called ionization potential. The subject is discussed in A. Sommerfeld's *Atombau und Spektrallinien* (Braunschweig, 1919); in N. R. Campbell's *Series Spectra* (Cambridge, 1921); in A. Fowler's *Report on Series in Line Spectra* (London, 1922); in W. M. Hicks' *A Treatise on the Analysis of Spectra* (Cambridge, 1922); and P. D. Foote and L. F. Mohler's *The Origin of Spectra* (New York, 1922).

Band spectra are assumed to be produced by molecules, spark spectra by ionized atoms, and arc and flame spectra by neutral atoms. Hence, W. Kossel³ and A. Sommerfeld infer that the spark spectrum of an element corresponds with the arc spectrum of the preceding element in the periodic table. This has been discussed by E. Fuess, A. Sommerfeld, and W. Reis. There have been a number of attempts—by R. Thalen, L. de Boisbaudran, G. J. Stoney, G. Salet, A. S. Herschel, and T. N. Thiele—to find relations in the band spectra of the elements and compounds. H. Deslandres gave for the frequencies of the lines making up a single band

$$\nu = A + Bm^2$$

where m is a successive series of integers; and A and B are constant, A representing the head of the band when $m=0$. The formula was tested by H. Kayser and C. Runge, but it does not accurately represent the facts—particularly for small values of m . Other formulæ have been proposed by G. Higgs, G. Halm, C. Fabry, and P. Weiss. A theoretical foundation for the formula was laid by N. Bjerrum on the assumption that (i) band spectra are produced by the rotational energy of rigid polyatomic molecules; and (ii) the emission and absorption of radiant energy in band spectra represent changes in the rotational energy which occur in accord with the quantum theory.

In equation (7) (3. 27, 3), it is shown that the kinetic energy, W , of a rigid molecule of mass m , rotating in a circular orbit of radius r , with an angular velocity ω , is $W = 2\pi m r^2 \omega^2$, and since the angular momentum $2\pi m r^2 \omega = \frac{1}{2} n h / \pi$, it follows on substituting for ω , $W = n^2 h^2 / 8\pi^2 m r^2$; and remembering that $W/h = \nu$, it follows that the frequency of the lines in two states of the particle should be

$$\nu = \frac{h}{8\pi^2 m r^2} (n_1^2 - n_2^2)$$

which is similar in type to H. Deslandres' formula, when n_1 and n_2 are integers corresponding with two states of the molecule. The formula was further improved by allowing for the fact that molecules are not really rigid bodies. A. Sommerfeld, A. Eucken, H. M. Randall, E. S. Imes, W. W. Sleator, E. Gehrcke and L. C. Glaser, and W. Lenz have discussed the application of the quantum theory to band spectra.

The action of a magnetic field on spectral lines.—P. Zeeman⁴ found that when the light from a Bunsen's flame coloured with lithium carbonate or sodium flame is passed between the paraboloidal poles of an electromagnet, the spectrum,

FIG. 3.—Effect of Magnetic Field on the Spectral Lines of Zinc and Cadmium—Zeeman's Effect.

with a grating of 14,938 lines per inch, showed that the two sodium lines, or the red lithium lines, are widened every time the current was turned on, and narrowed when the current was cut off. The sodium lines were widened on both sides to about $\frac{1}{40}$ th of the distance between the lines when in a magnetic field of an intensity of about 10^4 C.G.S. units. In general, the lines in the normal spectrum of an element are usually broadened into doublets, triplets, sextets, octets, or still more, complex groups when in an intense magnetic field. The effect will be evident from Fig. 3. Different lines of the elementary spectra are perturbed in different ways—some lines, originally single, may remain single; others give rise to doublets,

triplets, quartets, octets, etc. There is a certain pathetic interest attaching to this phenomenon—called the **Zeeman effect**—because the last experiment made by M. Faraday (March 12, 1862) was an attempt to find if any spectral change could be detected when the source of the light is placed in a magnetic field.

The colourless gas flame ascended between the poles of the magnet, and the salts of sodium, lithium, etc., were used to give colour. A Nicol's polarizer was placed just before the intense magnetic field, and an analyzer at the other extreme of the apparatus. Then the electro-magnet was made, and unmade, but not the slightest trace of effect on or change in the lines in the spectrum was observed in any position of polarizer or analyzer.

Observations by A. Trève, A. J. Angström, L. Daniel, A. Secchi, J. Chautard, E. van Aubel, and P. Thénard were also abortive. In 1886, C. Fizeau noted that the spectral lines of a flame were broadened in a magnetic field. He said: Les phénomènes qui se manifestent sous l'action du magnétisme sont identiquement les mêmes que ceux produits par une élévation de température. M. Faraday's experiment failed because the only available magnet was not strong enough. **The perturbation of the spectral lines in a strong magnetic field is supposed to be due to alterations in the mode of vibrations of the subatomic particles under a magnetic stress.** The observed displacement depends on the strength of the magnetic field. If the spectrum be produced by the vibration of atoms of the same kind, it would be difficult to explain why the mode of vibration of atoms of the same kind can be altered in this way. It is more reasonable to suppose that **the different effects produced by a magnetic field on the different lines of the spectrum of a substance are due to the presence of different kinds of particles in the incandescent element.** This simply means that at the high temp. of the luminous object, the atoms of the element are dissociated into simpler sub-atoms, which are probably electrified. Owing to the fact that corresponding lines in the spectra of related elements—for instance, magnesium, zinc, cadmium—are similarly affected so that the groups of lines in the different spectra undergo the same modification, it is inferred that the vibrating corpuscles which produce the A_1, A_2, A_3, \dots lines in the spectrum of zinc are the same as the vibrating corpuscles which produce the A_1, A_2, A_3, \dots lines in the spectrum of cadmium, etc. Hence, not only is an atom a complex association of different corpuscles, but the atoms of allied elements probably contain certain groups of corpuscles, or sub-atoms, in common. "These observations," said T. Preston, "lend some support to the idea so long entertained merely as a speculation, that all the various kinds of matter, all the various so-called elements, may be built up in some way of the same fundamental substance."

The phenomenon has been studied by A. A. Michelson, T. Preston, A. Cornu, H. Becquerel and H. Deslandres, A. Cotton, A. Righi, C. Runge and F. Paschen, S. Popow, F. Paschen and E. Back, P. Ehrenfest, J. M. Burgers, and P. Debye. In general, (i) the lines of band spectra are not influenced by a magnetic field; (ii) the lines may be resolved into twins or triplets—a greater number may be obtained; (iii) the different lines belonging to the same element are not all affected in the same way; (iv) with related elements the related lines behave in a similar way; (v) the magnitude of the effect is proportional to the intensity of the magnetic field. H. A. Lorentz, W. Voigt, A. Sommerfeld, H. A. Kramers, N. Bohr, and K. F. Herzfeld have developed the theory of the main features of the Zeeman effect. A. Sommerfeld, P. Das, etc., applied the quantum theory to Zeeman's effect. Assuming that light is produced in the atom by electrons oscillating about a positive nucleus—*vide infra*—it follows that the frequency of this vibration should be affected by a magnetic field because the latter must oppose or aid the centripetal force which is exerted by the positive nucleus on the rotating electron according as the direction of rotation is clockwise or anti-clockwise with respect to the lines of magnetic force. Hence, instead of a one-line spectrum two or three lines are produced, the two outer ones being produced by the vibrations of electrons whose orbits are deflected right and left with respect to the lines of magnetic force. The

central line has the same frequency as that of the original line, because it is produced by electrons whose orbits are situated in a plane parallel to the direction of the lines of magnetic force. The values of the ratio e/m are computed from $2(\nu_1 - \nu_2)\pi V^2/H = e/m$, deduced by H. A. Lorentz. Here ν_1 and ν_2 refer to the vibration frequency of the two outer spectral lines; V denotes the velocity of light; and H is the strength of the magnetic field. The results so obtained agree well with those obtained by measurements on the cathode rays.

The action of a magnetic field on polarized light.—A similar explanation applies to the observed rotation of the plane of polarized light by a magnetic field, first observed by M. Faraday,⁵ and hence called the **Faraday effect**. The effect has been the subject of numerous investigations. The influence of temp. has been investigated by E. Bichat,⁶ etc.; and the influence of chemical composition by W. H. Perkin,⁷ etc.

The action of an electric field on spectral lines.—Prior to 1913, no one had been able to show that an intense electric field had any influence on the spectral lines. A gas is always an electrical conductor when it is emitting a spectrum; there was therefore a difficulty in maintaining a sufficiently intense electric field to obtain a measurable displacement. J. Stark,⁸ however, succeeded in applying an electric field to a beam of canal rays and found that with hydrogen each line was resolved into a number of components which increased with the frequency of the line. Similar results were obtained with helium. The phenomenon is known as the **Stark effect**. Almost simultaneously, and yet independently of J. Stark, L. Surdo also succeeded in observing the effect in the cathode dark space of a discharge tube. The theory based on the atoms embodying positive nuclei each with a set of revolving electrons was worked out by K. Schwarzschild, and P. S. Epstein. The subject is discussed by A. Sommerfeld, L. Silberstein, and N. R. Campbell. G. Hettner shows that if the diatomic molecules of a gas have an electrical moment, there should be a shift and a splitting of the spectral lines in the external electrical field.

In absorption spectra, it is supposed that light is absorbed by the body, and that some particles are stimulated into sympathetic vibration, so that they vibrate about a position of equilibrium. P. Drude⁹ assumed that every molecule contains a number of electrons equal to the sum of the valencies of the atoms in the molecule, and also an ion or ions with a total positive charge equal to the sum of the negative charges. He showed that the harmonic vibration of electrons causes an absorption band, and influences the index of refraction in the neighbourhood. The periods of vibration of the electrons were assumed to be in the ultra-violet, and those of the ions or charged atoms in the infra-red. R. A. Houstoun derived a formula for m/e from the variation of the absorption coeff., and found it agreed in some cases with values of that ratio derived from other sources. Hence, he inferred that the absorption spectra of such soln. is produced by the vibrations of interatomic electrons; with aq. soln. of cobalt chloride, and uranyl nitrate, the results agreed better with the assumption that the vibrating particles have atomic dimensions. With cobalt chloride in aq. soln. it is supposed that the positively charged cobalt atom vibrates harmonically with the negatively charged chlorine atoms under the influence of electrical attractions. If, however, cobalt chloride be ionized the vibration of the cobalt atom will cease, and the cobalt ion cannot have a spectrum unless it be supposed that the vibrations occur inside the atom (electrons), or that the cobalt ion has surrounding water molecules.

The spectra of stars and nebulae.—The nature of the spectrum of an incandescent body depends upon the temp.; and since the spectra of many elements have been observed at several different temp., it is possible to get a rough idea of the temp. of any incandescent element from the appearance of its spectrum. For instance, the flame spectrum of sodium has two yellow lines close together, while the spark spectrum has a pair of lines in the orange and in the green; the flame spectrum of thallium has a single green line, and the spark spectrum has in addition

some bands in the violet. This fact is explained by the assumption that at the higher temp., the atoms of an element are aggregates of sub-atoms, each of which has its own characteristic mode of vibration. The spectra of the nebulae, stars, and suns thus enable rough approximations of their temp. to be made.

The sun, stars, and nebulae, said A. M. Clerke,¹⁰ form so many celestial laboratories where the nature and mutual relations of the chemical elements may be tried by more stringent tests than sublunary conditions afford. Astronomers tell us that the nebulae are the material out of which stars are made, and that in their forms, aggregations, and condensations, the process of evolution of stars and suns can be traced. The nebulae begin either as hot attenuated gases or as clouds of cold meteoric stones which gradually gain heat as they clash together, until finally they are converted into gases, and then gradually cool by radiation. Hence, the cooler stars are either young or old, heating up or cooling down. The hottest stars are in their prime. In the very hottest stars with an estimated temp. of 25,000°—*e.g.* β -Crucis—comparatively few chemical elements can be detected, while in the cooler red stars—*e.g.* Betelgeuse—the number of spectral lines is comparatively large, and a large number of elements are present. New elements appear to be introduced at each stage in the cooling of hot stars, so that elements which were non-existent in the hotter stars make their appearance in the cooler stars; and a few elements disappear in passing from the hot to the cooler stars.

In the hotter stars little more than hydrogen can be detected, then follow hot stars with calcium, magnesium, and a few other elements superadded; then come cooler stars with more complex spectra corresponding with a greater variety of elements. The planets, of which our own is a type, are among the cooler orbs. If the different suns and stars be arranged in a series, **the order of the appearance of the elements in the cooling stars is approximately the order of their increasing complexity as deduced from the magnitude of their atomic weights.** The lightest elements alone appear in the hotter stars. These facts fit very well into the hypothesis that the matter of which stars are made, passes through a real change in the nature of the constituent elements, and that there is a progressive tendency of the elements to assume more stable forms in passing from the hotter to the cooler stars. This corresponds with the assumption that the atoms are built of particles which form more and more complex aggregates as the temp. falls. Carbon is an exception. It has a low at. wt., and yet it appears comparatively late, but the non-volatility of the solid element shows that the molecule is probably complex. Calcium (at. wt. 40) appears before sodium (at. wt. 23); this may be due to the fact that the stability of the system of corpuscles which form an atom not only depends upon the number but also upon the mode of arrangement of the corpuscles. In a general way, however, the elements appear in the cooling stars in the order of their increasing at. wt. The stars may thus be arranged in groups corresponding with different stages in their development. The hydrogen-helium stars pass by insensible gradations into stars of the solar type, and finally into the deep red stars. This is illustrated by Table II, due to J. N. Lockyer.

TABLE II.—STELLAR TEMPERATURES.

	Spectrum.	Temperature.	Appearance of the elements.
Gaseous stars .	Longest	Highest	Hydrogen, helium, asterium (a gas not known on earth).
Metallic stars .	Medium	Medium	(a) Feeble spectrum of helium and hydrogen; magnesium; calcium; silicon and oxygen. (b) No gases of the helium family; iron; manganese; nickel; copper; etc.
Carbon stars .	Shortest	Lowest	Carbon and compounds of carbon.

Astronomers consider that the different stages in the evolution of sidereal systems cannot be demonstrated by the slow cooling of a *single* star, because the span of human life relative to the duration of cosmical events is far too short to enable the different stages to be followed in succession; these different stages can rather be followed by arranging the different nebulae in a series so as to show all gradations, from a diffuse luminous haze to stars with faint nebulous halos. The spectra of the gaseous and presumably younger nebulae consist of three lines corresponding with hydrogen, helium, and some unknown elements—the great nebula in Orion is usually given as an example. As the nebulae grow older and more compact, more lines corresponding with other elements appear. These spectra are supposed to represent clusters of corpuscles more stable than the rest. Hence, according to **J. N. Lockyer's evolution hypothesis**, the spectra of a properly arranged series of stars and nebulae indicate that **the chemical atoms have grown during the cooling of the primal ultra-atomic gas much as visible rain drops grow from invisible water vapour**. Before hydrogen appeared, a whole series of lighter elements were probably formed by the gradual condensation (polymerization, etc.) of the cooling "fire-mist," and then passed into the heavier and more complex elements as the temperature fell still lower. From a chemical point of view, therefore, the cooling of the primal matter has resulted in the formation of a succession of polymers $(1, 2, 3, \dots)\eta$, where η is the density of the hypothetical protyle. The polymerization may also proceed in successive stages. $A=(1, 2, 3, \dots)x$; $B=(1, 2, 3, \dots)y$; $C=(1, 2, 3, \dots)z$; . . . where x, y, z, \dots represent the densities of simple forms of matter. These complexes unite to form the series:

$$An, Bm, Cp, \dots; AB, BC, \dots; ABC, \dots$$

where n, m, p, \dots are integers. The light elements—*asterium, coronium, nebulium*, etc.—which appear to be present in some of the more attenuated nebulae, and in the hotter stars, have probably long since vanished from the earth. We infer their existence from their characteristic spectra. Helium was once included in the list of light stellar elements unknown on earth.

There is not much room for doubt about the theory with respect to the cooling of hot stars, but with nebulae, S. Arrhenius considers that the great *cold* reigning in space has condensed all but the lighter elements into solid or liquid state, and these have gravitated to the interior. The outer layer only is rendered luminous by dust particles and corpuscles flying into the nebula from space.

The hypothesis which is supposed to correlate these and other facts, is as follows: Long before the earth was formed, it is supposed that a kind of ultra-gaseous protyle was suffused throughout space, and, what has been called the temp. of the protyle, was inconceivably hotter than anything at present known on earth. In course of time, some process, akin to cooling, reduced the temp. of the protyle so that it was condensed into material atoms. The simplest elements most nearly allied to the protyle would naturally condense first—thus, hydrogen and helium with their low at. wt. were born. Then followed the elements next in order of complexity until finally uranium or radium was born. We do not know an element with a greater at. wt. and presumably a more complex structure. If the ideas developed in the chapter on the architecture of the atom approximate to the truth, even this element is not stable, and is slowly breaking down into simpler more stable forms. As the temp. fell still lower, the earlier formed elements would unite among themselves and produce chemical compounds. It is possible to reverse the process and dissociate chemical compounds by elevating the temp., but it has not been possible to raise the temp. high enough to verify the hypothesis by dissociating the elements.

§ 4. Electric Discharges in Attenuated Gases

If a first step towards understanding the relations between æther and ponderable matter is to be made, it seems to me that the most hopeful foundation for it is knowledge derived from experiments on electricity in high vacuum.—LORD KELVIN (1893).

The study of the phenomena attending the passage of electricity through gases has led to astounding developments during the past twenty years, and abundantly justified Lord Kelvin's prognostication. Under ordinary conditions, gases are such poor conductors of electricity that they are classed as good insulators. In order to get electricity to pass through air at ordinary atm. press., an electrical press. approaching 30,000 volts per cm. is required; and as the press. of the air is diminished the voltage required to produce a discharge diminishes in almost exactly the same proportion. If a glass tube, about 30 cm. long, Fig. 4, be connected with a mercurial air pump, and the aluminium electrodes—disc and point—be connected with an ordinary induction coil and battery, either no spark, or thin zig-zag sparks will pass through the tube; all depends on the distance of the electrodes apart, and on the electric press. produced by the coil. If the pump be started, the spark passes more and more readily as exhaustion proceeds; first, forked brush-like bluish sparks begin to leap from electrode to electrode; when the press. reaches

FIG. 4.—The Effect of an Electric Discharge on Attenuated Gases.

40 mm. of mercury, a luminous red streamer appears; the red line widens, forming a fuzzy strip between the electrodes; when the exhaustion is such that the press. is about 10 mm., a luminous band fills the whole tube, and a violet halo surrounds the two electrodes. At 6 mm. press., the band begins to break up into layers; at 3 mm. press., the tube appears to be filled with a number of transverse flickering reddish striæ, alternately light and dark. Glass tubes of about this degree of exhaustion—Geissler's tubes—are made in numerous patterns, and with different kinds of glass so as to get different fluorescent effects. Tubes containing gases under reduced press. and arranged for the passage of an electric discharge are called *vacuum tubes*. As exhaustion proceeds, the violet haloes about the electrodes grow larger and larger, and, as M. Faraday¹ noted in 1838, a dark space—**Faraday's dark space**—appears at the negative electrode. The prevailing colour of the pulsating striæ depends on the nature of the gas in the tube—with hydrogen the colour is red, and with chlorine green. The aureole about the cathode—called the **negative glow**—separates from the flickering striæ, and a dark space—**Crookes' dark space**—appears between the negative glow and the cathode, Fig. 4. This was observed by J. Plücker in 1858, and described by W. Crookes in 1879. The luminous striæ stretching beyond Faraday's dark space is called the **positive column**. The length of Crookes' dark space, the negative glow, and Faraday's dark space do not depend very markedly on the length of the tube; in long tubes the positive column occupies most of the tube—for example, in a tube 2000 cm. long, the positive column may occupy all but about 3 cm. As the exhaustion continues, the striæ diminish in

number and size; and they appear to be paler in colour. The light at the anode dwindles down to a luminous point, and Crookes' dark space at the cathode soon expands, and finally fills the tube. The glass then acquires a greenish-yellow phosphorescent light if the tube is made of soda glass. The press. is then about 0.33 mm. of mercury. J. Plücker first observed the walls of the discharge tube near its cathode glowed with a phosphorescent light. With further exhaustion the tube looks as if it were empty, but the glass still glows brightly, particularly about the cathode. With still further exhaustions, the current from the induction coil is unable to pass through the vacuum tube. The fact that the tube when highly evacuated is non-conducting shows that *the electric current must somehow be carried from one electrode to the other by something*, otherwise action at a distance is possible.

J. Stark and W. Hermann,² E. Goldstein, E. Wiedemann and A. Pospisloff, W. Matthies, E. Gehrcke and R. Seeliger, etc., have investigated the colour and spectra of the negative glow with various gases and vapours. The negative glow with *hydrogen* is bluish-white and it shows two spectra and Balmer's series; with *nitrogen* the colour is violet-blue, and it shows band and line spectra; with *helium* the colour is green, and with *argon* blue, while both show line spectra; with *neon* the colour is red; with *oxygen* the colour is greyish or yellowish-white, and it shows a band spectrum; with *carbon monoxide* the colour is greyish-white, and there is a band spectrum; with *carbon dioxide*, the colour is sky-blue; with *chlorine* the colour is green, yellowish-green with *bromine*, and orange-yellow with *iodine*, bromine and iodine give a band spectrum. With *sodium* the colour is yellow, and it gives the D-line; with *potassium* the colour is pale blue, with *rubidium* blue, and with *cæsium* greenish or greyish-white, and all give line spectra; with the vapours of *cadmium* and *zinc* the glow is red, and there are line spectra; and with *mercury* vapour, the colour is green or white, and it gives a line spectrum.

§ 5. Cathode and Lenard Rays

The electron has conquered physics, and many worship the new idol rather blindly.—H. POINCARÉ (1907).

Whoever rejects faith in the reality of atoms and electrons, or the electro-magnetic nature of light waves, or the identity of heat and motion, cannot be found guilty of a logical or empirical contradiction; but he will find it difficult from his standpoint to advance physical knowledge.—M. PLANCK (1913).

W. A. Hittorf¹ showed that if a solid body—say a Maltese cross made of mica—be placed between the anode, *A*, and cathode, *C*, as in Fig. 5, a true shadow appears on the glass when the tube is evacuated; the shape of the cross shows that something must travel from the neighbourhood of the cathode in straight lines. This "something" which causes the phosphorescence of glass was called by E. Goldstein *Kathodenstrahlen*—**cathode rays**. Hence, (1) *the cathode rays travel in straight lines normal to the surface of the cathode; and they will cast a well-defined shadow if a solid object be placed between the cathode and the wall of the vacuum tube*. The experiment can be varied in an ingenious manner, as shown by W. Crookes, Fig. 6, by arranging the stream of cathode rays so that it strikes the upper vanes of a little paddle wheel which then rolls horizontally along a pair of parallel glass rails, away from the cathode. By

reversing the electric current, the wheel stops and then revolves in the opposite direction owing to the fact that the direction of the cathode stream has been reversed. Hence, (2) *cathode rays can exert mechanical pressure*. By directing the cathode rays on to different minerals, W. Crookes showed that beautiful phosphorescent effects may be obtained. Crystals of perthite, and didymium glass give a red phosphorescence; artificial rubies, and willemite a green phosphorescence; scheelite, yellow; Iceland spar, white; barium platinocyanide, zinc blende, etc., also glow and phosphoresce when exposed to the rays. Hence, (3) *many minerals become phosphorescent when exposed to the cathode rays*. The spectra of phosphorescent

FIG. 5.—Shadows Cast by Cathode Rays. FIG. 6.—Mechanical Motion by Cathode Rays.

rare earths are of great value in studying these compounds. E. Wiedemann and G. C. Schmidt found that even when no visible coloration is produced by the cathode rays, a body after exposure is often so changed that when, subsequently weeks or even months afterwards, it is warmed it becomes luminous—thermo-luminescence—at a temp. far below that at which it becomes luminous in the normal state. There is sometimes, also, an after-glow which lingers for a time after the bombardment has ceased. E. Wiedemann and G. C. Schmidt's results are indicated in Table III. W. Crookes also showed that the cathode stream, when focussed

on platinum by means of a cathode shaped like a concave mirror, may heat the metal white hot, glass can be melted, diamonds charred, etc. Hence, (4) *the cathode rays raise the temperature of bodies on which they fall*. Measurements of the heat developed by the rays have been made by E. Wiedemann and co-workers, P. Ewers, etc. E. Goldstein found that if the cathode stream be allowed to impinge on white rock-salt or lithium chloride these salts are coloured violet. The glass of the vacuum

tube is also coloured after long use. E. Wiedemann and G. C. Schmidt, J. Elster and H. Geitel, etc., have investigated this subject. P. Villard found that cathode rays exert a reducing action on cupric oxide. It is not always easy to distinguish chemical effects produced by the incidence of the rays from the secondary effects due to the heat produced by the rays. Platinum acquires a film of platinum black after long exposure to the rays. Hence, (5) *the cathode rays can produce chemical and physical changes*. H. von Helmholtz noted that a point discharge on a jet of steam results in the condensation of drops of water; F. Richarz found that condensation of steam is produced by the action of an electrical discharge. J. S. Townsend showed that electrified gases produce a fog when admitted into a vessel containing aq. vapour; and C. T. R. Wilson found that if a stream of electrons be directed into an atm. of moist air, each electron serves as a nucleus about which moisture collects, and each electron becomes the centre of a visible drop of water. Hence, (6) *a stream of electrons, when directed into moist air, forms a cloud*. The cloud or mist is an aggregate of minute falling raindrops; and it is assumed that, like a particle of dust in moist air an electron in moist air can serve as a nucleus for the condensation of the water vapour. E. Goldstein showed that the cathode rays can be reflected when they strike a surface at various angles of incidence. L. W. Austin and H. Starke found the different metals of sp. gr. *D* the percentage amounts *R* of the incident rays which are reflected:

	Pt	Pb	Ag	Bi	Ni	Cu	Fe	Zn	Al	Mg
<i>R</i>	72	63	59	54	48	45	43	40	25	25
<i>D</i>	21.5	11.3	10.5	9.9	8.9	8.5	7.7	7.1	2.6	1.7

The proportion of cathode rays reflected is roughly proportional to the square root of the sp. gr. of the metal. W. Seitz measured the percentage reflection with different angles of incidence of the cathode rays; A. Becker, A. A. C. Swinton, H. Starke, E. Wiedemann and P. Ewers, W. Cady, P. Ewers, E. Merritt, E. Gehrcke, G. E. Leit-häuser, S. Williams, etc., have studied the reflected cathode rays. The diffusion of the cathode rays was investigated by P. Lenard, J. Robinson, etc. M. E. Tressler has discussed the uses of the cathode rays, and J. J. Thomson the uses of electrons.

In 1895, J. Perrin arranged a vacuum tube so that the cathode stream passed into a small metal cylinder inside the tube, and, by means of a wire, he connected the inner cylinder with an external electroscope. The electroscope acquired a gradually increasing negative charge, or a positively charged electroscope was discharged. Hence, (7) *the cathode rays are negatively electrified while the other contents of the tube are positively electrified*. E. Goldstein, W. Crookes, and E. Wiedemann and H. Ebert studied the mutual deflection of two cathode streams in the vicinity of one another. J. Plücker showed (8) *the cathode rays can be deflected from their normal course by means of a magnet*. This is illustrated by Fig. 7, for if a magnet be directed to the side of the tube through which a discharge is passing, the focus of the rays can be deflected on to the walls of the tube. The heat produced by the bombardment of the walls of the tube by the cathode stream will suffice to melt a little wax placed on the outside of the tube. A. K. Birkeland found that the cathode rays are not only deflected by a magnet, but they are also broken up into several distinct patches or groups, giving a kind of magnetic spectrum studied by R. J. Strutt, J. J. Thomson, etc.

H. Hertz found that when thin films of gold leaf or aluminium are interposed in the track of the cathode rays, they show an appreciable phosphorescence on the

FIG. 7.—The Effect of Magnet on Cathode Rays.

reverse side of the plate, thus indicating that the cathode rays are in part transmitted through the thin metal. P. Lenard made a tube with a thin aluminium sheet—*D*, Fig. 8—carried by a brass cap, at the end opposite the cathode *C*; a metal cylinder, *A*, served as anode.

FIG. 8.—Lenard's Tube to bring the Cathode Rays outside the Vacuum Tube.

P. Lenard found that the cathode rays passed through the aluminium window outside the tube; they were then called **Lenard rays**. The cathode or Lenard rays are absorbed by different metals used as windows—the absorptive power of a substance is almost directly proportional to its density. If the metal window is too thick, the cathode stream is arrested. Hence, (9) *the cathode rays can penetrate and pass through thin sheets of metal, but not through thick sheets*. The subject was studied by W. Seitz. The loss in velocity of cathode rays in passing through thin metal

plates was studied by G. E. Leithauser and T. Descoudres. P. Lenard measured the absorptive power of different substances for the cathode rays, and expressed the absorption, *A*, in terms of the amount absorbed by a layer of substance of 1 sq. cm. section and 1 grm. in weight.

	H (3.3 mm.)	H (760 mm.)	Air (0.73 mm.)	Air (760 mm.)	SO ₂ (760 mm.)	Al	Mica	Ag	Au
<i>A</i>	0.00149	0.476	0.00416	3.42	8.51	7150	7250	32200	55600
<i>D</i>	0.0,368	0.0,849	0.0,125	0.00123	0.00271	2.70	2.80	10.5	19.3

The ratio *A/D* is roughly 3200 (mean). Measurements were made by A. Becker, W. Kaufmann, etc.

C. F. Varley suggested that the cathode rays are composed of “attenuated particles of matter, projected from the negative pole by electricity,” and in virtue of their negative charges, these particles are affected by a magnet. About eight years afterwards, W. Crookes suggested that they were particles or mols. of a **fourth state of matter**—an ultra-gaseous state which was called **radiant matter**—in which the free paths of the mols. were so long that collisions could be disregarded. W. Crookes showed that the so-called Crookes’ dark space at very high exhaustions may occupy the whole tube, and he suggested that the thickness of this dark space may be a measure of the mean length of the free path of the particles. “The extra velocity with which the mols. rebound from the excited negative pole keeps back the more slowly moving mols. which are advancing towards that pole. The conflict occurs at the boundary of the dark space when the luminous column bears witness of the energy of the collisions. He attributed the fluorescence of the walls of the tube to the impact of the particles on the glass. W. Crookes’ idea was that the cathode rays are ordinary gaseous mols. carrying electric charges, and in which the free path is so long that collisions may be disregarded. E. Wiedemann, E. Goldstein, H. Hertz, etc., did not accept the molecular torrent theory of the cathode rays, but regarded them as due to disturbances in the æther.

Owing to their high penetrative power (Lenard rays), and the fact that no difference in the properties of electrons can be detected by changing the kind of gas in the evacuated tube, or by changing the electrodes, it follows that (10) *the cathode rays are independent of the kind of matter present; and if the particles be matter at all, the matter is the same in kind, from whatever source it is derived*. In 1842, R. Phillips asked: May not electricity be an atomic compound minus some of the ordinary properties of matter? M. Faraday had previously answered (1835).

The atoms of matter are in some way endowed or associated with electrical powers to which they owe their most striking qualities, and amongst them their mutual chemical affinity. . . . The equivalent weights of bodies are simply those quantities of them which contain equal quantities of electricity or have naturally equal electric powers; it being electricity which determines the equivalent number because it determines the combining force. Or, if we adopt the atomic theory or phaseology, then the atoms of bodies which

are equivalent to each other in their ordinary chemical action, have equal quantities of electricity naturally associated with them. But, I must confess I am jealous of the term *atom*; for although it is very easy to talk of atoms, it is very difficult to form a clear idea of their nature.

W. Weber attributed electrical phenomena to the agency of stationary or moving charges which could be pictured as discrete and atomic; he said:

The relation of the two particles as regards their motions is determined by the ratio of their masses e and e' , on the assumption that in e and e' are included the masses of the ponderable atoms which are attached to the electrical atoms. Let e be the positive electrical particle. Let the negative be exactly equal and opposite, and therefore denoted by $-e$ (instead of e'). But let a ponderable atom be attracted to the latter so that its mass is thereby so greatly increased as to make the mass of the positive particle vanishingly small in comparison. The particle $-e$ may then be thought of as at rest, and the particle $+e$ as in motion about the particle $-e$. The two unlike particles in the condition described constitute then an Amperian molecular current.

H. von Helmholtz revived the atomistic conception in 1881. He said:

The same definite quantity of either positive electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion. If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity.

Likewise O. J. Lodge emphasized the same idea four years later. Lord Kelvin also said that Faraday's laws necessitate something atomic in electricity. E. Wiechert, and J. J. Thomson suggested the startling hypothesis that what W. Crookes called "radiant matter" or **the cathode rays, is a stream of negatively charged particles or corpuscles which have been formed by the disintegration of atoms of the gas in the vacuum tube.** The term **electron** was applied by G. J. Stoney to designate the unit or atomic charge of electricity. Nature, said he, presents us with a single definite quantity of electricity; for, in electrolysis, each chemical bond which is ruptured within an electrolyte, a certain quantity of electricity traverses the electrolyte, and this quantity is the same in all cases. It is now almost universally applied to the sub-atomic particles supposed to stream from the negative electrode when a discharge is passing through an attenuated gas. No difference can be detected in the corpuscles derived from different gases, and hence it is inferred that **the electrons are common constituents of all gases.**

According to hypothesis, the electric discharge in attenuated gases splits the atoms of the gas into positively and negatively charged electrons. **The cathode rays are a stream of negatively charged electrons sent from the cathode with a high velocity.** It is inferred that ordinary atoms are probably made of nothing but aggregates of sub-atomic particles—positively and negatively charged. J. Larmor said:

Electricity is atomic in nature. . . . Electrons are centres of strain in the æther. . . . Matter consists of clusters of electrons in orbital motion round one another.

Under ordinary conditions, the charges counteract one another and the atom is electrically neutral. By the action of an electrical discharge, negative electrons are supposed to be detached from the atom, leaving a residue with a positive charge, and called a **positive electron** or positive ion. If a negative electron attaches itself to a neutral atom, the latter will acquire a negative charge. In reviewing the evidence derived from the properties of cathode rays J. J. Thomson said: "The explanation which seems to me to account for the facts in the most simple and straightforward way is founded on the view of the constitution of the chemical elements which has been favourably entertained by many chemists." The view is that **the atoms of the different chemical elements contain different aggregations of particles of the same kind**; otherwise expressed, that a part at least of all atoms consists of electrons.

Although the sign and magnitude of the electric charge carried by an ion in the electrolysis of soln. is constant and invariable—the hydrogen ion is always positively charged, H^+ , and the chlorine ion negatively charged Cl^- —J. J. Thomson has emphasized the fact that in the electrolysis of gases the signs of the charges carried by different atoms of the same element are not always the same, for hydrogen atoms may carry positive or negative charges. The atoms of the elements, however, have a specific attraction for the different charges, so that a hydrogen atom attracts a positive charge more powerfully than a negative charge, and a chlorine atom on the contrary attracts a negative charge more powerfully than a positive charge.

One C.G.S. electromagnetic unit of current is 10 amp. ; one C.G.S. electrostatic unit of current = $\frac{1}{3} \times 10^{-9}$ amp. One ampère = $\frac{1}{10}$ th electromagnetic unit = 3×10^9 electrostatic units. One electromagnetic unit of quantity = 10 coulombs. Hence, one electrostatic unit of current = $\frac{1}{3} \times 10^{-9}$ coulombs, or one coulomb = $\frac{1}{3} \times 10^9$ electromagnetic unit = 3×10^9 electrostatic units. One electromagnetic unit of resistance is 10^{-9} ohms, and one electrostatic unit is 9×10^{11} ohms. Hence, one ohm = 10^9 electromagnetic units = $\frac{1}{9} \times 10^{-11}$ electrostatic units. One C.G.S. electromagnetic unit of press. = 10^{-8} volts, and one electrostatic unit of press. = 300 volts. Hence, 1 volt = 10^8 electromagnetic units = $\frac{1}{300}$ electrostatic unit. One electromagnetic unit of capacity = 10^9 farads, and one electrostatic unit of capacity = $\frac{1}{9} \times 10^{-11}$ farads. A microfarad = 10^{-6} farads.

Experiments have shown that in all probability the electric charge on an ion formed in the process of electrolysis, is the same as the electric charge of an electron. The ionic theory of electrolysis shows that atoms or groups of atoms carry electric charges which are integral multiples of the unit charge borne by an atom of hydrogen. The electric charge carried by 1.008 grm. of hydrogen is 96,540 coulombs. The number of atoms in a gram-ion of hydrogen is 6.06×10^{23} . Hence, the unit charge per atom is $e = 96540 \div 6.06 \times 10^{23} = 1.57 \times 10^{-19}$ coulombs ; but one coulomb = 10^{-1} electromagnetic units, or 3×10^9 electrostatic units ; hence, the charge on a univalent ion in electrolysis may be expressed as 1.57×10^{-20} electromagnetic units or 4.78×10^{-10} electrostatic units. *In electrolysis, the ratio of the charge, e, to the mass, m, of the hydrogen ion, e/m, is 9.654×10^3 electromagnetic units per gram.* The charge on the electron is 4.7×10^{-10} electrostatic units, or 1.56×10^{-20} electromagnetic units, and for gases the ratio of the charge, e, to the mass, m, of the electron, e/m, is 1.774×10^7 electromagnetic units per gram. Hence, $9.654 \times 10^3 \div 1.774 \times 10^7 = \frac{1}{1840}$ nearly, meaning that the mass of a hydrogen ion is 1840 times the mass of an electron or negatively charged corpuscle ; and therefore **the mass of an electron is $\frac{1}{1840}$ th the mass of a hydrogen atom**—i.e. 8.9×10^{-28} grms. ; its diameter is about 3.7×10^{-13} cms., whereas an atom of hydrogen has a mass, m, or about 1.64×10^{-24} grms. The diameter of a molecule of hydrogen is about 2×10^{-8} cms., so that compared with the atom, the electron has quite a microscopic size. The electrons travel with a velocity ranging from 10^7 to 10^9 cms. per sec., or nearly 90,000 miles per second. Their speed is dependent upon the intensity of the electrical force passing through the vacuum tube. A cathode particle travelling at this speed could go nearly twice round the earth in a second. The idea that the electrical condition of matter and its chemical activity depend upon the addition or removal of electrons from atoms of molecules has been incorporated with the ionic hypothesis, and with the modern theory of the structure of the atom. A. Günther-Schulze has discussed the condition of electrons in electrolytic ions ; H. F. Mayer, C. Ramsäuer, P. Lenard, and H. Akesson, the reactions of gas molecules with free electrons.

§ 6. Röntgen or X-rays

We shall never succeed in exhausting unmeasurable nature.—A. VON HUMBOLDT.

When the exhaustion of a vacuum tube is such that the tube is on the verge of becoming electrically non-conducting, and the glass opposite the cathode is brilliantly fluorescent, rays proceed from the fluorescent glass, *outside the tube*; these rays—called **X-rays** or **Röntgen rays**—have quite different properties from the cathode or Lenard rays, because they will pass through glass, and they are not deflected by a magnet. In a typical X-ray tube, there are generally but not essentially two anodes; one of these, called the *anticathode* or target, is arranged to collect the rays from the cathode and to reflect and focus the resulting X-rays outside the tube. Like rays of light, the Röntgen rays can be reflected, refracted, and polarized; and they are not appreciably affected by the most powerful electric or magnetic fields as a stream of charged particles would be. **Röntgen rays are produced by the destruction of the cathode rays, and are formed when the cathode rays suddenly change their velocity**; and conversely, as L. Simons showed, a substance bombarded by X-rays may furnish cathode or β -rays. Every substance when bombarded by electrons emits Röntgen rays—the glass walls of a vacuum tube, heavy metals like platinum or uranium, etc. W. Wolff¹ found that Lenard's rays are accompanied by some X-rays. The X-rays travel in straight lines with a velocity not far from that of light. It is supposed that Röntgen rays—like the rays of light, radiant heat, and electromagnetic waves—are due to pulses or waves set up in the æther by the impact of electrons on matter. It is all a question of frequency or wave-length. Table IV gives the wave-lengths of a number of radiations, so as to show the relation of the X-rays to other kinds of ray. Hence the wave-length of the X-ray is about a thousand times smaller than the wave-length of sodium light, and is comparable with the size of the atom.

When X-rays of sufficient penetrating power are made to impinge on a substance, the latter itself becomes a source of X-rays which are called **secondary X-rays**. In

TABLE IV.—WAVE-LENGTHS OF SOME RADIATIONS.

Radiation.	Wave-length in cm.
Electromagnetic waves of wireless telegraphy . .	3×10^3 to 5×10^4
Longest heat waves known	6×10^{-3}
Infra-red spectrum	6×10^{-3} to 7.5×10^{-5}
Red spectrum	6×10^{-5}
Green spectrum	5×10^{-5}
Violet spectrum	4×10^{-5}
Ultra-violet radiations	4×10^{-5} to 2×10^{-6}
Schumann's waves	10^{-6} to 2×10^{-6}
Röntgen rays	10^{-8} to 10^{-9}

general, the secondary rays have very different penetrating powers from the exciting or **primary X-rays**. Only a small proportion of the cathode rays are effective in producing primary X-rays; the general efficiency of the conversion is low, for the X-rays are but a small by-product of the energy transformations in the tube. A. S. Eve and S. H. Day estimate that of the energy supplied to an ordinary X-ray tube, about 0.005 per cent. is contained in the X-rays. J. J. Thomson deduced that the energy of an X-ray is proportional to the fourth power of the velocity of the exciting cathode ray; and this was confirmed by the experiments of R. Whiddington; but R. T. Beatty found that while the relation may hold good for primary radiations, it is not valid for the so-called characteristic radiations (*vide infra*), for which the energy = $0.000051A\beta^2E$, where A denotes the at. wt. of the anti-cathode, β , the velocity of the cathode rays expressed as a fraction of the velocity of light (3×10^{10} cms. per sec.), and E , the energy of the parent cathode rays.

In his paper *Ueber eine neue Art von Strahlen*, the discoverer of the X-rays, W. C. Röntgen (1895) found that they can excite fluorescence on a paper-screen coated with barium cyanoplatinate, BaPtCy_4 , or calcium tungstate, CaWO_4 ; they can fog a photographic plate; and make the air through which they pass a conductor of electricity. The quantity of charge carried by the ions of conducting air is not always the same. The sum of the charges of a given sign carried by all the ions is often used as a measure of the quantity of radiation which has produced the charge. Since the sum of the positive charges is equal to the sum of the negative charges, it is merely a matter of expediency which sign of charge is used in the measurement. The amount of ionization produced in a gas in a given time depends (i) on the inverse square of the distance from the excitor (E. W. B. Gill); (ii) on the difference of potential applied to the tube (W. Hillers); (iii) on the penetrating ability of the rays (R. K. McClung, and C. G. Barkla); (iv) on the nature of the gas (J. A. Crowther); and on the press. of the gas (W. Hillers, R. K. McClung, and C. G. Barkla); but is independent of the temp. of the gas (J. A. Crowther, and J. H. Clo). E. F. Perreau, and G. Athanasiadis found that X-rays affect the electrical resistance of a selenium cell in the same manner as light rays.

Certain uranium and other compounds exhibit fluorescence when exposed to the action of X-rays. The excited fluorescence has a longer wave-length than the exciting X-rays. When the intensity of the radiation is increased as by bringing the object closer to the source, the intensity of the fluorescence is increased. W. C. Röntgen did not find any simple relation between the potential difference applied to the tube and the amount of fluorescence, but the two variables were in some cases directly proportional. In all cases, under constant conditions, the intensity of the fluorescent light varied inversely as the square of the distance between source and object. C. Schuhknecht, and A. Dahms obtained a visible fluorescence with calcium oxide from marble (reddish); cadmium iodide (greenish); mercurous iodide (reddish); barium fluoride, fluoroiodide, cyanoplatinate (yellowish-green), and sulphide; lead sulphate, iodide, sulphide, chromate, carbonate, nitrate,

and acetate; and zinc sulphide (yellowish or bluish-green). The spectrum of the ultra-violet fluorescence was observed with fluor-spar; scheelite; zinc sulphide; potassium, calcium, and barium cyanoplatinates; ammonium uranium fluoride; potassium uranium nitrate; lead sulphide; and zircon. The glass of X-ray tubes is coloured violet presumably due to the separation of colloidal manganese. Fluor-spar is coloured an intense blue (with cathode rays the colour is violet); when strongly heated, the coloration disappears with thermo-luminescence. G. Holzknecht observed colour changes were produced in sodium chloride, potassium bromide, etc., by exposure to X-rays; H. Bordier and J. Galimard, and W. B. Hardy and E. G. Willcock observed that iodine separates from soln. of iodine in chloroform or benzene by exposure to X-rays. The action of X-rays on silver bromide photographic plates has been discussed by R. Luther and W. A. Uschko, L. Zehnder, E. Marx, L. Cramer, etc. In general, an increase in the current sent through the exciting tube hastens photographic action; while an increase in the penetrating power of the rays makes the action slower. W. C. Röntgen and J. O. Heinze found that two X-rays which produce equal effects on a fluorescent screen, do not always produce the same effect on a photographic plate; and R. Luther and W. A. Uschko thought that they detected a difference in the action of light and of X-rays on a silver gelatino-bromide plate. L. Baumeister and R. Glocker found the liberation of iodine from soln. of iodoform in chloroform is not proportional to the energy of the incident X-rays. G. Schwartz found that X-rays precipitate calomel from a mixture of ammonium oxalate and mercuric chloride; various chloroplatinates were found by H. Bordier and J. Galimard, and G. Holzknecht to change colour when exposed to X-rays; and H. A. Colwell and S. Russ found that starch is changed by X-rays into soluble starch and then into dextrin. A. Dauvillier attributes the chemical actions of the X-rays to the destruction of the negative ions; the slow electrons expelled neutralize the neighbouring positive ions, and the electronegative and electropositive elements are thus liberated in the atomic state, or their valence is reduced—e.g. Cu^+ to Cu . Serious pathological changes are produced by the long-continued exposure of parts of the body to X-rays, so that an operator must protect himself most carefully.

The X-rays have a remarkable power of penetrating substances opaque to ordinary light. The penetrating power of Röntgen radiations refers to the decrease in the energy of a pencil of the rays which occurs when the rays are allowed to impinge on a given solid. The **equivalent transparency** of a substance to X-rays is the mass in decigrams of a right cylinder of one sq. cm. base, which, when traversed by X-rays parallel to the axis, produces the same absorption as a cylinder of paraffin wax 75 mm. high and 1 sq. cm. cross-section. The **penetrating power** of X-rays is usually characterized by measuring their absorption in a sheet of aluminium of definite thickness. If 1, 2, 3, . . . similar sheets are successively introduced, each sheet absorbs the same fraction of what it receives, so that there is no scattering or transformation of the rays, and if I_0 denotes the intensity of the normally incident beam; I , that of the emergent beam; and k , the fraction absorbed by unit area and unit thickness—the so-called **linear absorption coefficient**, or the **specific opacity**, then, for a plate of thickness d , it follows that $I = I_0 e^{-kd}$. If k is large, the rays are easily absorbed, and if k be small, the rays are very penetrating. Röntgen radiations with a low penetrative power, called *soft rays*, are emitted from a vacuum tube which has relatively much residual air. The supply of electrons is then plentiful; their speed is comparatively slow; and a current of comparatively low electromotive force is needed. Conversely, radiations with a high penetrative power, called *hard rays*, are emitted if the tube be very highly exhausted. The supply of electrons is then relatively small; their speed is comparatively high; and the necessary electromotive force is high. S. Ratner has discussed the hardening of X-ray tubes by prolonged use. For X-rays of average hardness, k lies between 4 and 8 cm^{-1} , and for hard rays between 2 and 4 cm^{-1} . If the absorption coeff. k be divided by the density D of the absorbent,

the ratio k/D is called the **mass-absorption coefficient**; it measures the absorption per unit mass for a normally incident ray of unit cross-section. This constant is more important because, as usually measured, the absorption is determined by mass alone. The sp. transparency of an element for X-rays of a definite hardness is a function of the at. wt., and is greater the smaller the at. wt. The absorption of X-rays has been studied by R. A. Houstoun, F. Butavand, R. Glocker, L. de Broglie, K. A. Wingardh, W. E. Williams and B. L. Worsnop, etc. J. L. Glasson found that the stopping power of an atom is proportional to $N^{\frac{1}{2}}$, where N is the at. number, rather than to $A^{\frac{1}{2}}$, where A is the at. wt.

The specific opacity, or its reciprocal, the eq. transparency of an element, for the X-rays is characteristic, and is independent of its state of aggregation, its temp., and whether it is free or compound. The property is therefore additive, so that if masses m_1, m_2, m_3, \dots of elements of sp. opacity O_1, O_2, O_3, \dots are present in a

total mass M and sp. opacity, O , then E , then $MO = m_1O_1 + m_2O_2 + m_3O_3 + \dots$. L. Benoist found that for X-rays of one definite quality, the sp. opacity decreases or the eq. transparency increases regularly with the at. wt., so that if either be plotted with the at. wt., the curve, Fig. 9, is obtained for X-rays of medium hardness. Each quantity of X-ray has its own particular curve; for instance, the dotted line, Fig. 9, is for soft rays. The curves can be used for estimating the at. wt. of an element. Each multiple of the combining wt. is used until one is found which lies on the curve. A. S. Eve and S. H. Day measured the absorption coeff. of soft, medium, and hard X-rays in air up to 100 metres for distances up to 10 metres, with soft rays, $k=0.0010$ to 0.0018 ; and k/D is 0.8 to 1.4 ; with medium rays, $k=0.00040$, and $k/D=0.32$; and with hard rays, $k=0.00029$ and $k/D=0.023$; and for distances between 40 and 60 metres, $k=0.00029$ and $k/D=0.23$ for medium rays; and $k=0.00014$, and $k/D=0.11$ for hard rays. The absorption by 1 cm. of air is eq. to that by $\frac{1}{350}$ cm. of water.

FIG. 9.—X-ray Transparency Curve of the Elements.

L. de Broglie gave $k\lambda^3N^4$ for the coeff. of at. absorption of the X-ray fluorescence, when N is the at. number. He also studied the thermodynamics of the absorption of X-rays. J. A. Becker investigated the effect of a magnetic field on the absorption of X-rays. Various penetrometers and qualimeters have been devised for measuring the hardness of X-rays. The **reflection** of the X-rays has been studied by W. H. Bragg, C. G. Darwin, W. L. Bragg and co-workers, A. H. Compton, B. Davis and W. M. Stempel, H. A. Wilson, etc.

When the cathode rays strike the anticathode target, they are not arrested instantly at the surface, but merely suffer retardation, so that they penetrate for some distance into the body of the target. The particles travelling in the body are more or less deflected, and, if for a given velocity of cathode rays, the target be made thicker and thicker, a stage will finally be reached at which the particles travel uniformly in all directions; this critical thickness is called the depth of complete scattering. J. A. Crowther and W. R. Ham found the thickness with copper and with silver is 0.001 cm., with gold, 0.0020 cm., with aluminium is 0.015 cm., and with lead, 0.00025 cm., when the voltage is $90,000$; but it varies

directly with the difference of potential across the tube. Those primary rays which are not absorbed by the target emerge into the vacuum space of the tube. C. G. Barkla and T. Ayres, and E. A. Owen studied the distribution of the scattered rays. C. G. Barkla found that if the difference of potential across the tube is small, the primary rays have a maximum intensity in a direction perpendicular to the cathode stream, and a minimum intensity parallel to that stream. The effect is called the *polarization of the X-rays*. As the difference of potential increases, the polarization decreases and finally vanishes. It is assumed that at the higher potentials the rays formed by the initial retardation of the cathode stream are negligible in their effects compared with those which come out in all directions from the depth of complete scattering. C. G. Barkla and J. G. Dunlop found the **co-efficient of scattering**, s —defined in an analogous way to the coeff. of absorption k —is roughly proportional to the sp. gr. D , so that s/D is nearly constant 0.2. For elements of high at. wt., s/D increases slightly with at. wt. for hard rays and considerably so with soft rays. For a homogeneous radiation the absorption coeff. has to be amended to $s-k$. When a substance is exposed to a beam of X-rays, the emergent rays are scattered or deviated in direction, and the substance gives off so-called characteristic, monochromatic, or homogeneous X-rays. At the same time negatively charged corpuscular rays are formed. The scattered X-rays have been studied by C. G. Barkla and co-workers, J. A. Crowther, W. L. Bragg and co-workers, J. J. Thomson, C. W. Hewlett, T. E. van Auren, F. Dessauer and F. Vierheller, J. A. Gray, R. Blondlot, H. Haga, E. Bassler, J. Herwig, L. Vegard, W. R. Ham, F. C. Miller, etc. The rays emitted from an ordinary bulb are usually heterogeneous, both hard and soft, but C. G. Barkla and C. A. Sadler showed that radiators may be roughly divided into four groups:

Group 1, including the elements hydrogen to sulphur ranged in the order of their at. wt. When excited by a beam from a soft tube the members of this group give off little, if any, real secondary radiation, but rather a scattered radiation which is of the same nature as the exciting beam, and which is polarized in a plane perpendicular to the direction of the parent cathode stream. If the tube is made moderately hard, then a slight amount of true secondary radiation shows itself, and if the tube is very hard, a well-defined secondary beam is given off having a penetrating ability much different from that of the exciting rays.

Group 2, chromium to zinc. This group gives off a beam composed almost entirely of a true homogeneous secondary radiation even when excited by rays from a soft tube, but this radiation has little penetrating ability. With a given excitation, the ionization produced by it is almost 100 times that produced by an equal mass belonging to the first group.

Group 3, silver to iodine. If the exciting beam is only of moderate penetrating ability, this group gives off mostly a scattered radiation, but, unlike that from the first group, it is unpolarized, and there is a noticeable amount of true secondary radiation present. The relative amounts of scattered and secondary radiation vary greatly with small changes in the character of the exciting rays.

Group 4, tungsten to bismuth. These substances resemble group 2 in their action. For all the above elements the penetrating ability of the true secondary rays is independent of the intensity or of the penetrating ability of the exciting beam, but is a periodic function of the at. wt. of the radiating elements.

J. A. Crowther found that if the radiator is a chemical compound, the component atoms and radicals determine the character of the secondary rays produced. J. L. Glasson showed that the rays coming from salts are composed of (1) a homogeneous radiation having the same penetrating ability as that from the metal itself, and (2) a more penetrating scattered primary radiation due to the acid radical. If a metal occurs in the acid radical it has no individual effect, but merely acts along with the rest of the radical.

C. G. Barkla and C. A. Sadler showed that if the incident primary X-rays are less penetrating than the secondary radiations characteristic of a given radiator, no secondary rays are produced; but if the incident primary rays are more penetrating than the secondary radiation, secondary rays are produced. The analogy between the development of secondary X-rays with the production of fluorescent light has been emphasized by calling the former *fluorescent X-rays*. It was also

shown that if the stimulus be great enough, every substance can be made to emit a set of X-rays which can be regarded as homogeneous and characteristic. The quality of these characteristic rays depends on the substance and not on the exciting X-rays, provided the exciting rays are harder than the characteristic radiation. The penetrating power of these rays increases with the at. wt. of the metal from which they are emitted; and the characteristic radiation of an atom can excite the corresponding radiation of a lighter atom, but not that of a heavier atom. Under suitable conditions, many, possibly all, elements can emit at least two sets of characteristic radiations which C. G. Barkla distinguished as the **K-radiations** and the **L-radiations**. The former are about 300 times more penetrating than the latter.

In addition to the *K*- and *L*-homogeneous radiations, H. G. J. Moseley and C. G. Darwin, and W. H. Bragg found that platinum and some other metals give out a third type; M. Siegbahn observed an *M*-series with the elements of high at. wt. The mean wave-length of the *M*-series is four times as great as that of the *L*-series. J. Laub found that iron, copper, and zinc give what he called *I*-series of radiations, which with the metals named have $k/D = 43.9, 23.8$, and 18.5 respectively. C. G. Barkla and M. P. White, C. M. Williams, and A. W. Hull and M. Rice observed discontinuities in the absorption coeff. of certain metals for X-rays of short wave-length, and they inferred the existence of a *J*-series of radiations. W. Duane and T. Shimizu observed no such discontinuity with aluminium, and F. K. Richtmeyer and co-workers obtained none with the other elements. It is therefore inferred that there is no evidence of *J*-radiations.

The greater the at. wt. of the metal emitting the *K*- and *L*-rays, the harder the rays. Elements with a high at. wt. readily furnish the *L*-radiation—this is the case with the elements ranging in the order of their at. wt. from zinc to uranium; and

FIG. 10.—Relation between the Mass Absorption Coefficient of X-rays and the Atomic Weight of the Metal emitting the Radiation.

the *K*-radiations, from sodium to tungsten. According to R. Whiddington, and J. C. Chapman, there is a relation between the two series, in that if an element of at. wt. A has an *L*-radiation of a certain hardness, then the at. wt. A_K of an element whose *K*-radiation has the same hardness, is, $A_K = \frac{1}{2}(A_L - 48)$. If this be correct, no element with an at. wt. less than 48 can have an *L*-radiation. Fig. 10 shows the relation between the at. wt. of the metal emitting the radiation and the mass absorption coeff. of the characteristic radiations in aluminium, including some γ -radiations from radioactive elements by E. Rutherford and co-workers. The observations of J. Chadwick and A. S. Russell, J. A. Gray, and

H. Richardson are included in the diagram. If the logarithms of the two variables are plotted, two straight lines are obtained. E. A. Owen found that the penetrability of the radiations in aluminium are roughly proportional to the fifth power of the at. wt. of the metal emitting the radiation.

J. C. Chapman and co-workers, and J. L. Glasson showed that the characteristic X-rays are independent of temp. or of chemical combination. Ferric oxide, or sulphate, ferrosiferrous oxide, and potassium ferrocyanide, all give iron rays of the same quality; tin nitrate similarly gives the tin rays; and methyl iodide and ethyl bromide vapours give characteristic iodine and bromine radiations when struck by hard X-rays. This shows that the X-ray phenomenon is purely atomic.

J. C. Chapman and S. H. Piper tried to find if the secondary radiation persisted

after the primary radiation has ceased, but not $\frac{1}{250}$ th of the original radiation can be detected $\frac{1}{3000}$ th of a second after the exciting primary rays were cut off. Since the primary rays from the target of an X-ray tube must pass through a certain thickness of the target before they can emerge, R. T. Beatty found as anticipated that such rays would excite that secondary radiation which is characteristic of the substance used as a target. There is some evidence to show that the cathode stream itself may cause the target to give off its characteristic radiation if the velocity of the cathode stream is large enough. W. R. Ham has been able, by the use of proper absorbers, to filter out the secondary rays coming from his tube, leaving only the primary rays. He found that the ratio of the secondary radiation to the primary was increased by an increase in the potential difference across the tube. The rays coming from an ordinary X-ray tube are therefore heterogeneous, and since the potential difference necessary to cause a discharge to pass through the tube varies with the condition of the tube this heterogeneity is constantly changing. X-ray spectra have been discussed by L. de Broglie, A. Dauvillier, G. Hertz, E. Gehrcke and E. Lau, F. C. Hoyt, J. E. Lilienfeld, G. Zecher, H. Behnken, N. Stenstson, W. Kossel, A. Sommerfeld, M. Siegbahn, A. Smekal, E. Hjalmar, H. Fricke, W. Duane and R. A. Patterson, R. Whiddington, W. Duane and T. Shimizu, W. Duane and K. F. Hu, E. Hjalmar, W. H. Bragg, G. Wentzel, E. H. Kurth, J. A. Crowther, F. L. Mohler and P. D. Foote, D. Coster, etc.

If a correction be made for the scattering of the *K*- or *L*-series of X-rays which impinge on a metal, C. G. Barkla and C. A. Sadler showed that the ratio of the absorption by any two metals is approximately constant and is not dependent on the quality of the radiation, provided that such radiation does not excite the characteristic radiations of either metal. Thus C. G. Barkla and V. Collier found that the absorption by carbon for all types of X-ray is 0.11 when corrected for scattering—if not corrected, the absorption for soft rays is 0.11, and for hard rays, 0.41. G. W. C. Kaye studied the absorption of X-rays of various qualities of a particular metal, and found that the absorption decreases steadily as the rays are hardened, but the absorption

reaches a minimum for rays identical in quality with the *K*- or *L*-characteristic radiations; and for rays a little harder than these, the absorption increases rapidly, and becomes permanently larger. C. G. Barkla and V. Collier also showed that the absorption of the X-rays from nickel increases steadily with the at. wt. of the absorbing metal so long as the *K*- and *L*-characteristic radiations are excited; when the at. wt. of the absorbing metal is so high that its *K*-characteristic ceases to be

excited, the absorption suddenly drops. The increase is repeated until the *L*-radiation ceases to be excited, as shown in Fig. 11. E. A. Owen, and C. G. Barkla and V. Collier measured the absorption of characteristic X-rays by various gases and vapours—air, carbon dioxide, sulphur dioxide, ethyl bromide, and methyl iodide.

The X-rays are reflected by atoms in proportion to the at. wt. of the atoms struck. W. H. Bragg assumed the law of reflection to be $n\lambda = 2d \sin \theta$, a formula which he employed in his study of the action of X-rays on crystals—1. 11, 3. E. Hjalmar, and P. P. Ewald have studied the accuracy of the formula. The at. reflection in a body whose atoms are not organized into a crystalline structure

FIG. 11.—Relation between the Absorption of X-rays from Nickel and the Atomic Weight of the Absorbing Metal.

resembles the scattering of light by a fog. The at. reflection from a crystal furnishes a diffraction spectra analogous to that of light when a sufficiently fine atomic lattice, such as that furnished by the atoms of a crystal, is used as a grating. The diffraction of X-rays was not successfully accomplished until M. von Laue had shown that the difficulties arising from the extreme shortness of the wave-length

FIG. 12.—X-ray Spectra of some Elements.

could be overcome by utilizing the regular grouping of the atoms in a crystal as a kind of diffraction grating—*vide* 1. 11, 8. As a result, X-ray spectra, using anti-cathodes of the different elements, have been obtained. The phenomena have been employed in investigation on the minute structure of crystals. H. G. J. Moseley photographed the X-ray spectra of different elements. With the lighter elements emitting strong *K*-radiations, the wave-length decreases as the at. wt. diminishes; and the spectrum contains at least two lines of which the line of longer wave-length called the α -line is the more intense; the β -line comes next in order of intensity. H. G. J. Moseley's results are indicated in Table V. The *L*-radiations, Table V, give spectra made up of at least five lines— $\alpha, \beta, \gamma, \delta, \epsilon$ —reckoned in order of decreasing wave-length and decreasing intensity. The α -line in the *K*-spectrum is really a doublet; and there are a number of other fainter lines in both the *K*- and *L*-series of spectra. This is illustrated by Fig. 12.

TABLE V.—WAVE-LENGTHS OF THE TWO PRINCIPAL LINES IN THE X-RAY SPECTRA OF THE ELEMENTS.

H. G. J. Moseley further showed that when the increase in the at. wt. of the element is plotted with the logarithm of the corresponding decrease in wave-length, the curve does not run smoothly; but if the square roots of the vibration frequencies be plotted against a series of natural numbers, the curve runs almost smoothly. The numbers, called **atomic numbers**, represent very closely the order of the elements in the periodic table. The at. number is nearly half the at. wt. At. numbers are not mere integers, but represent a fundamental property of the atoms, because if at. wt. are employed in place of at. numbers, the relationships shown in Fig. 13

are not nearly so satisfactory. Similarly also with several other physical properties. It is, however, putting the blind eye to the telescope to pretend that the substitution removes the anomalies in the periodic classification on the chemical side emphasized 1, 6, . . . That Chapter remains unaffected by the substitution. M. Duvallier has discussed this subject.

The wave-length of the X-ray is inversely proportional to $(N-a)^2$, where N is the at. number, and a is a constant; or the frequency or $\nu = b(N-a)^2$, where a and b are constants. Fig. 13 shows the results for the K - and L -radiations. No known element is left unprovided in the scheme, and the harmony in the relationship justifies the assumption that certain blanks may be regarded as representing yet undiscovered elements. In the range from hydrogen to gold there are blanks for three new elements—one between molybdenum and ruthenium; another between lutecium and tantalum; and one between tungsten and osmium. The order of the atomic numbers is that of the at. wt. except in the cases of argon, cobalt, and tellurium.

H. G. J. Moseley's work has been extended by M. Siegbahn and E. Friman, and W. Stenström, and the K -series has been followed down to sodium, and the L -series down to zinc and up to uranium.

The relation between the vibration frequency and the at. number has been discussed by G. A. Anslow and co-workers; H. E. Ives and O. Stuhlmann, C. Runge and H. Precht, H. Bcll. H. S. Allen, and W. Kossel. G. le Bas, R. Ledoux-Lebard and A. Dauvillier, T. E. van Auren, G. A. Anslow, W. Duane, etc. L. Vegard inferred that since it is possible to predict some X-ray frequencies as functions of the at. wt., the atom contains plane rings of electrons; but A. Smekal denies this. The relation between the at. wt. and the at. number was discussed by R. G. Durrant, and W. D. Harkins and E. D. Wilson. The relation between the L -series of spectra and at. wt. was developed by F. Kirchhof.

The order of the at. numbers is the same as the order of the at. wt. except where the latter disagrees with the order of the chemical properties so that the at. number in the periodic table is a more fundamental index of quality than the at. wt. **The wave-length, or the vibration frequency, of the characteristic X-rays from different elements changes from element to element by regular jumps.** The steady decrease in the wave-length of the characteristic X-rays of a series of elements in the periodic table depends on some fundamental property of the atoms. As pointed

FIG. 13.—Moseley's Relation between the Atomic Number and Frequency of K - and L -radiations.

out by W. Kossel, the continuity of the *K*-line spectra of the different elements from the lowest to the highest at. number, shows that the periodicity observed in the outer valency electrons does not extend to the innermost electrons. As an hypothesis, it has been suggested that the increments are due to the successive addition of a unit electric charge to the nucleus of the atom; and that the magnitude of the nucleus of an atom is proportional to a number—the at. number—indicating the place of the element in the periodic table—hydrogen has a nucleus charge of one unit, helium two, etc. This shows that the wave-length of a characteristic radiation depends entirely on the magnitude of the nuclear charge of the atom which in turn depends on the at. number. J. Chadwick found that the nuclear charge of a platinum atom is 77.4, the at. number is 78; while the nuclear charges of silver and copper atoms are 46.3 and 29.3, when the at. numbers are respectively 47 and 29. The same at. number may be borne by several elements with different at. wt., and in the case of radioactive substances, with different stabilities. These elements may be inseparable by the ordinary chemical or physical tests. These elements are the isotopes of F. Soddy; and they presumably have in common the same nuclear charge. The isotopes might also be expected to yield the same X-ray spectrum. E. Rutherford and E. N. da C. Andrade found the spectrum of the soft rays from radium-*B*, is identical with the *L*-radiation of lead.

§ 7. The Photoelectric Effect

According to the quantum theory of energy—*vide* 1. 13, 15—the intensity of the disturbance produced by the appropriate type of incident light must exceed a certain limiting value before any light can be emitted; it is impossible for a radiator to emit any energy when the supply of energy is less than one quantum. J. Franck and G. Hertz¹ bombarded a rarefied mercury vapour with cathode rays, so arranged that the electrons had a definite and determinable velocity dependent upon the difference of potential between the electrodes. So long as the difference of potential was less than 4.9 volts, the emitted light gave an ill-defined continuous spectrum, but at 4.9 volts, a single bright line appeared of wave-length 2536.72 Å. Calculations show that at the critical moment when the light appears, the energy of the negative particles constituting these rays is equal to that required by the quantum theory, namely $h\nu$, where h is M. Planck's constant 6.62×10^{-27} erg. sec., and ν is the vibration frequency, *i.e.* $\nu = 39410$. When the voltage reaches 6.7, a band of wave-length 1849.6, or vibration frequency 54066, appears; and with the voltage 10.4, other lines appear; but, according to J. C. McLennan, the lines 1849.6 and 2536.72 did not appear. H. L. Dodge describes the following qualitative experiment in further illustration of the hypothesis that definite units of energy are required to produce light of any specified wave-length:

An exhausted bulb, containing a trace of gas, is placed near a coil traversed by a rapidly alternating current. The bulb becomes the secondary of a transformer, and the tendency is for currents to be set up in the gas. If the bulb is placed close to the coil it experiences a strong field, while if it is withdrawn a little the field is weakened. If the bulb is more

than a certain distance away, the light given out is diffused throughout the whole tube; but on the critical limit being passed, a brilliant ring of light springs into being inside the bulb. The ring disappears just as abruptly as the distance is again increased, being in all cases either exceedingly bright or entirely absent. The spectrum of the light from such a bulb also changes abruptly with the appearance and disappearance of the ring. The same general effect is produced with different gases, but the spectrum and the strength of the field at which the ring appears are different for each gas and characteristic of the gas. It is also found that the absorption of energy changes abruptly with the appearance of the ring, at which time the conductivity of the gas suddenly increases, resulting in a larger current and a corresponding increase in the absorption of energy.

The photoelectric effect—described 2. 18, 5—whereby a surface illuminated by ultra-violet light becomes positively charged and facilitates the passage of electricity in such a direction as to charge the surface positively, is explained as being due to the emission of electrons. P. Lenard discovered the remarkable fact that the maximum velocity of the emitted electrons does not depend on the intensity of the illumination no matter whether this intensity is varied by altering the distance of the source of illumination, or by introducing absorbing screens. Rather does the velocity of the ejected electrons depend on the vibration frequency of the incident light. The number of electrons emitted per sec. per unit area, increases with the intensity of the incident monochromatic light. The phenomena are discussed in H. S. Allen's *Photoelectricity* (London, 1913), and in A. L. Hughes' *Photoelectricity* (Cambridge, 1914). Let V denote the velocity of the emitted electron, and m its mass; let W denote the work required to get the electron through the surface of the metal, i.e. the latent heat of evaporation of the electrons per electron, at absolute zero of temp. The energy required for the expulsion of the electron comes from the incident light, and on the basis of M. Planck's quantum theory, this must be equal to $h\nu$. The kinetic energy of the electron is $\frac{1}{2}mV^2$, hence

$$h\nu = W + \frac{1}{2}mV^2$$

If P denotes the difference of potential through which the electrons must pass in order to acquire the velocity V , and e the electric charge on an electron, 4.774×10^{-10} electrostatic units, the relation between kinetic energy of the electron as it leaves the metal is equal to the product of the charge, e , by the potential P , or $Pe = \frac{1}{2}mV^2$;

$$P = \frac{h\nu}{e} - \frac{W}{e}$$

This relation can be tested experimentally. The value of W can be obtained from thermoelectric data combined with the temp. variation of the rate of emission of electrons when the metal is heated. For platinum, F. Deininger obtained $W = 5.03$ volts; H. A. Wilson, 5.39 volts; and O. W. Richardson, 5.61 volts—average, 5.34 volts or 8.32×10^{-12} ergs. A. L. Hughes measured the relation between W and ν . The values of P and the corresponding frequencies have been measured by O. W. Richardson and K. T. Compton, and others. R. A. Millikan measured the minimum positive potential necessary to be applied to the illuminated surface in order to prevent the emission of electrons. The observed value h/e is within five per cent. of that calculated in other ways; and the general results confirm the quantum theory of radiation. The tube-of-force or æther-string theory does not explain the phenomena.

The relation between photochemical reactions and A. Einstein's theory has been previously discussed—vide 2. 18, 5. J. Plotnikoff has shown that on calculating the energy absorbed by one mol, from light of various wave-lengths, the extreme ultra-violet, $100\mu\mu$, gives up 300,000 cals. and X-rays 3×10^9 cals., which indicates that with decreasing wave-length light becomes much more active, until with X-rays, all mols. will be simply destroyed. Further, all atoms in all reactions in all solvents must react with the same velocity at all temp., and must take up the same quantity of energy. A number of other photochemical reactions deviate 9 to 22 per cent. from Einstein's law, and this is taken to show that

this law in its present form cannot be maintained. With the photolyses of hydrogen iodide and bromide the law is in approximate agreement with facts since the divergence varies only between -3.3 and 4.0 per cent. G. Kornfeld showed that in the case of hydrogen dioxide, the law fails because the decomposition is not a primary light effect.

The ejection of electrons from solids bombarded by X-rays may be regarded as a kind of photochemical effect, for here the velocity of the emitted electrons is proportional to the difference of potential between the electrodes of the tube producing the rays. The harder the X-rays, the greater the velocity of the emitted electrons. Assuming that the X-rays transfer a quantum of energy from an electron bombarding the anode of the X-ray tube to the surface on which the X-ray impinges, then, since $Pe=h\nu$, and $\nu=V_\infty/\lambda$, where V_∞ denotes the velocity of light, 3×10^{10} cms. per sec., and λ denotes the wave-length of the X-ray, $Pe=hV_\infty/\lambda$. With a voltage $P=40,000$, i.e. $40,000\div 300$ electrostatic units, it follows, on substituting the values indicated above for h , V_∞ , e , and P , that $\lambda=3\times 10^{-9}$ cms.—a result in agreement with that obtained in other ways.

Besides the *normal photoelectric effect*, on which the number of electrons liberated by light of a given intensity and frequency depends only on the amount of light absorbed by the metal, there is the *selective photoelectric effect*, exhibited by the alkali metals, in which this number is a maximum for some particular frequency of light, and is less for frequencies either greater or smaller. The frequency at which the maximum emission occurs is characteristic of the exposed metal surface, and decreases with decreasing at. wt. Similarly, too, with the X-rays, with a certain definite voltage in the exciting tube, there occurs an abnormal emission of electrons from the surface exposed to the X-rays, and the frequency of the X-rays required to produce this abnormal emission is nearly proportional to the at. wt. of the exposed metal. O. J. Lodge discussed the critical velocity, critical frequency, and critical distance of electrons at the moment of their liberation from molecules stimulated by light.

Isaac Newton's corpuscular theory of light was abandoned in favour of the æther-wave theory. The former failed to explain interference phenomena; electromagnetic waves; and phenomena associated with the velocity of light. A. Einstein's equation is based on a kind of corpuscular theory of light. The equation explains phenomena which do not fit the æther wave-theory so well. Nevertheless, added R. A. Millikan:

The physical theory of which A. Einstein's equation was designed to be the symbolic expression, is so untenable that A. Einstein himself no longer holds to it, and we are in the position of having built a very perfect structure, and then knocked out entirely the underpinning without causing the building to fall. It stands complete and apparently well tested, but without any visible means of support. These supports must obviously exist, and the most fascinating problem of modern physics is to find them. . . . The atomic and electronic worlds have revealed themselves with beautiful definiteness and wonderful distinctness, but their relation to the world of æther waves is still a profound mystery.

C. Ramsauer devised a test to find if the existence of energy in definite quanta in the form of trains of light waves, gives rise to the quantum emission of photoelectrons. He concluded that the quantum-like behaviour of photochemical processes must be the result of the mechanical processes of absorption of the light energy taking place in the atom, and is certainly not caused by single light-quanta present in the wave-trains of the light as definite entities. C. F. Bickerdike discussed the relation between radiation electrons and the æther.

§ 8. The Radiation Theory of Chemical Action

The speed of chemical reactions varies with the conc. of the reacting molecules; in the simple case of a unimolecular reaction commencing with a mols of material, the amount of substance dx which disappears in the time dt is equal to the conc. x at the time t , when x of a has been transformed. Consequently, $dx/dt = -k(a-x)$, where k is the so-called velocity constant. Otherwise expressed, $x = a(1 - e^{-kt})$. This is the expression, in mathematical language, of L. Wilhelmy's law that the speed of chemical action is proportional to the amount of substance taking part in the reaction. Why do not all molecules undergo change at one time? What regulates the speed of the reaction in such a way that only a certain fraction of the total number of molecules changes in unit time? If all the molecules were in the same condition, then either no chemical change would take place at all, or else all the molecules would undergo transformation at the same instant.

According to the kinetic theory, a certain number of molecules, at any given instant, possess a much greater, and others a much smaller, velocity of translation than the average. J. W. Mellor¹ assumed that the kinetic energy of translatory motion may be converted into energy of atomic vibrations; when the latter exceeds a certain limiting value, the atoms take up a more stable configuration. The rate of chemical action then depends on the rate at which the velocities of the molecules are accelerated beyond the limiting value. S. Arrhenius represented the effect of temp., $T^\circ \text{K.}$, on the velocity constant k , by $d \log k/dt = AT^{-2}$; and he showed that a rise of 10° may cause the velocity of a reaction to be augmented 200 to 300 per cent. under conditions where the collision frequency of the molecule is only 2 per cent. It is therefore certain that the effect of a rise of temp. on these reactions is not to be explained as the effect of an accelerated speed of molecular motion, but rather as inducing a change in the internal energy of the molecules. It has generally been assumed that the molecules are activated in some way before they react, and that this activation is the one affected by temp. A in S. Arrhenius' equation is half the energy required to change a mol of the assumed inactive modification to the active form. This leads to the effect of catalysts. S. Arrhenius predicted that the temp. coeff. should be diminished in a homogeneous system by increasing the conc. of the catalyst. W. C. McC. Lewis found the temp. coeff. of the speed of hydrolysis of methyl acetate is independent of the conc. of the acid. H. S. Taylor also doubted the existence of activated molecules. According to E. Marcellin, when the internal energy of a molecule reaches or exceeds a certain critical value, the molecule is capable of reacting chemically. The additional energy which a molecule in the mean or average state must receive in order to make it reactive, can be called the *critical increment*. On these assumptions, he deduced a formula resembling that of S. Arrhenius' $d \log k/dT = E/RT^2$, where E represents the critical energy that must be absorbed by a molecule to render it active. J. Rice developed the relation $d \log k/dT = (V_c - V_m + \frac{1}{2}RT)/RT^2$, where V_m is the mean value of the potential energy of the molecule, V_c is the critical value it must attain before chemical action can occur. R. C. Tolman has also studied the kinetics of the radiation theory of chemical action. N. R. Dhar argues that the general experience that reactions with the largest temp. coeff. are also most sensitive to light, fits the radiation hypothesis. From observations on the effect of ultra-violet light the absorption spectra, E. C. C. Baly assumed that in the process of activation the bonds between the atoms or atomic groupings are loosened.

J. Perrin, and W. C. McC. Lewis have assumed that *energy of the radiation type is the ultimate source of all the energy which makes chemical reactions possible; every chemical reaction is produced by radiations having a specific wave-length.* With reactions which proceed at ordinary temp. it is assumed that short infra-red radiation is effective, and such is necessarily present throughout a material system in virtue of its temp., for the temp. of a substance is directly due to radiation which is being continually absorbed and emitted by the constituent molecules. Only at absolute zero will such radiation be absent. The effective radiation with reactions which proceed only at high temp. presumably belong to the visible or ultra-violet region. The assumption that radiation is the *fons et origo* of all reactions which occur at ordinary temp. is different, though similar to that involved in the so-called photochemical reactions discussed in 2. 18, 5. In photochemical reactions, the energy applied is usually largely in excess of the net energy involved in the reaction, whereas with the intra-red absorption the energy increment is not a large fraction of the chemical energy of the reaction. According to G. N. Lewis, in each molecule there are two sets of charged particles capable of acting as oscillators, (i) the positively charged nuclei and (ii) the electron. On account of the relatively high mass of the positive particles, it seems probable that they are never, or almost never, capable of vibrating with a frequency sufficiently high to come within the scope of the visible spectrum, but they rather cause absorption in the ultra-red. On the other hand, those light and indeed almost massless particles called electrons are usually held lightly enough, so that their natural period is well above that of the visible spectrum, and they can therefore absorb in the ultra-violet region. Thus, in the great majority of chemical compounds which are colourless, the positive parts have too low a frequency and the negative parts too high a frequency to affect the visible spectrum. If, however, the constraints under which the electrons are held are in some way loosened, their frequency of vibration will diminish, and then ultimately they may become so loosely held as to absorb in the visible spectrum.

W. C. McC. Lewis has developed the hypothesis that *the rate at which a substance decomposes or interacts depends not only on its concentration, but simultaneously upon the density of that type of radiation which the substance can absorb;* and he has applied Einstein's theory of radiation. The critical increment of a molecule is one quantum of absorbable radiant energy; and A. Einstein's law of photochemical equivalency, then enables the effect of temp. on the velocity constant to be calculated; and conversely, from the observed effect of temp. on the velocity of a reaction it is possible to compute a value for the wave-length of the radiation which a substance is capable of absorbing and by means of which the reaction is activated. The hypothesis also enables the heat of the reaction to be calculated. He calculated the energy increment from R. Marcellin's formula which in the hydrolysis of methyl acetate at 25° and 35°, assumes the form $\log k_{35} - \log k_{25} = E/R(\frac{1}{298} - \frac{1}{308})$. This gives $E = 16,800$ cal. per mol, or 1.03×10^{-12} ergs per molecule. From Einstein's law, and W. W. Coblentz's value $\lambda = 7.5\mu$ for the infra-red radiation of methyl acetate, $h\nu = 0.262 \times 10^{-12}$ ergs, and therefore $4h\nu$ should supply the required energy. He also showed from the probable free-path and the electrolytic velocity of the H⁺-ion, that it would have a vibration frequency falling in the region of the known absorption.

W. C. McC. Lewis' hypothesis is in conformity with M. Trautz's work and with that of H. Krüger, who explained the process of soln., soln. press., solubility, and ionization on the basis of radiation; and showed that the last is related with the dielectric constant of the solvent. The velocity constant of a reaction depends on the cube of the index of refraction of the system for the wave-length of the absorbed radiations which cause the chemical change. There is a close relation between the refractive index and the dielectric capacity of a medium; hence also there is a close relation between the dielectric capacity of the medium in which the reaction proceeds. The function of a catalyst, said W. C. McC. Lewis, is to absorb

infra-red radiations and transfer their energy to the reacting molecules. Catalysis is thus a special case of a chemical reaction where the absorption is effected largely by the catalyst instead of by the reacting substance. Reactions taking place in soln. are regarded as catalytic. This, however, is doubtful. With uncatalyzed homogeneous bimolecular gas reactions, like $2\text{HI}=\text{H}_2+\text{I}_2$, the agreement with theory is satisfactory, for in that case the index of refraction is nearly unity in conformity with Einstein's law. In heterogeneous catalytic reactions, the energy increment is lowered at the contact surface, as indicated in I. Langmuir's hypothesis of the distribution of the molecules and atoms at the interface between two surfaces. In the case of unimolecular reactions, like the dissociation of phosphine, the agreement with theory is very poor, for the observed velocity constant is 10^7 times greater than that calculated from Einstein's law on the assumption that absorption is continuous or discontinuous. S. Dushman and E. K. Rideal found an equation of the type $dN/dt=\nu e^{-h\nu/kt}$ to give good results with phosphine; here N is the number of molecules reacting per second; ν is the vibration frequency; and the other symbols have their usual signification. W. E. Garner believes the agreement rather due to chance than to compatibility of hypothesis.

E. C. C. Baly developed a theory of spectroscopic and fluorescent phenomena on the assumption that a molecule may absorb radiation by quanta of a given frequency, and as a result of chemical action it may radiate a larger number of quanta of lower frequency. He explained the thermal decomposition of phosphine, the photochemical decomposition of hydrogen peroxide, and the hydrolysis of acetone where chemical action is in excess of that calculated from Einstein's theory, by assuming that this internal radiation is re-absorbed, resulting in further chemical action. W. T. David showed that there is an infra-red radiation, $\lambda=2.8\mu$ and 4.4μ , during the explosive combination of oxygen with coal gas or hydrogen. The temp. of the reaction is 1200° , but it is assumed that the radiation is due to chemical action, and is not a temp. effect.

F. Daniels and E. H. Johnston's work on the thermal and actinic decomposition of gaseous nitrogen pentoxide which is unimolecular at room temp. showed that the critical increment is 24,700 cals., and it follows that the reaction should be catalyzed by light of wave-length $\lambda=1.16\mu$. This is not confirmed by observation. The reaction is accelerated by light of wave-length $\lambda=400-460\mu$, but only in the presence of nitrogen peroxide. It is suggested that the catalytic effect of nitrogen peroxide is due to its absorption of blue light over a wide spectral range, and through fluorescence, radiation is emitted in the infra-red region, where its absorption lines coincide with those of nitrogen pentoxide, causing the decomposition of the latter. This hypothesis has not been checked by observation.

If radiations of specific wave-length are alone effective in producing chemical reactions, it is a waste of energy to invoke the entire spectrum of radiations to produce a reaction dependent on temp. One fraction of the radiations may produce the desired reaction, and other fraction may produce a reverse reaction and so cancel the effect of the first. It therefore follows, as P. Weiss has shown, that instead of this crude method of activating chemical reactions, the more elegant and efficient procedure will involve a selection of the specific radiations required to produce the given effect.

I. Langmuir concluded that the radiation theory of chemical action is invalid because (i) it has not satisfactorily demonstrated that the radiation emitted by a chemical reaction, as calculated from the temp. coeff., falls in the absorption region of the system, for, in the case of hydrogen and certain colourless gases, there are no absorption bands at the frequencies predicted by the hypothesis; and (ii), as M. Polanyi has shown, the hypothesis is untenable because the total radiation is not nearly sufficient to account for chemical activation. The energy required for the unimolecular decomposition of phosphine is much greater than that calculated by the radiation laws as being supplied through the walls of the containing vessel at the calculated frequency. The laws which govern the temp. coeff. of a reaction

and the emission of monochromatic radiation are similar because they are both expressions of probabilities. A unimolecular reaction is independent of molecular collision because the time between collision is very great compared with the time of activity. The energy of activation cannot come from molecular collision, or from radiant energy emitted by the walls, but it must come from the latent internal energy of the molecule. Hence, said I. Langmuir, the internal energy of the molecule is the ultimate source of its activation. F. A. Lindemann also claimed that, according to the radiation theory, many reactions should be photosensitive which fail to exhibit the effect—for example, the inversion of sucrose is not affected by sunlight. W. C. McC. Lewis argued that the null effect of sunlight is due to the screening effect of a layer of the soln. T. W. J. Taylor tested the hypothesis with soln. of sucrose where the screening effect was eliminated and obtained a negative result. The objections have been discussed by W. C. McC. Lewis and A. McKeown. M. Polanyi tried to show that the quantum hypothesis is invalid when applied to chemical processes.

§ 9. Positive or Canal Rays

The corpuscular theory of the positive rays has no other justification than that it explains our present-day knowledge of the phenomenon in the simplest possible way.—E. GEHRCKE.

When a perforated cathode is employed in the vacuum tube for producing cathode rays, E. Goldstein ¹ first noticed that streams of violet light passed through the perforations or canals and emerged behind the cathode on the side remote from the anode, and hence he called these streams *Kanalstrahlen* (canal rays). In the apparatus illustrated in Fig. 14, the canal rays travelling towards the right strike against a plate *b* connected with an electroscope *B*, and there show a positive charge; the cathode rays travelling towards the left impinge on the plate *a* connected with an electroscope *A*, and there show a negative charge. The canal rays have been investigated by methods similar to those employed for the cathode rays. W. Wien,

P. Ewers, and P. Villard have shown that the canal rays are streams of particles the majority of which are positively electrified—hence, the term **positive rays** is replacing the older term **canal rays**. The streaming particles travel in straight lines and produce a phosphorescence (usually violet) when they impinge upon glass, etc.

FIG. 14.—Tube for Canal or Positive rays.

gas; positive rays in hydrogen gas exert a reducing action. H. P. Waran discussed the "sand-blast" action of the rays on glass. The theory of the canal rays has been discussed by G. Huch, A. Ruttenauer, G. Mie, etc.

A. Wehnelt showed that the positive rays of oxygen oxidize copper, but G. C. Schmidt found that the oxidation is not directly due to the impact of the rays, but is an indirect effect due to the production of active oxygen as the rays pass through the

H. Baerwald, V. F. Hess and M. Hornyak, and J. Stark have discussed ionization by canal rays. The speed of the positive electrons is usually less than that of the negative electrons; and they are not so sensitive to magnetic influences. Measurements similar to those employed for the cathode rays show that the positively charged particles must be of the atomic dimensions, and in no case is the mass of the positive ion perceptibly less than that of the hydrogen atom. W. Wein found for air, a velocity $V = 3.6 \times 10^7$ cms. per sec., and for the ratio e/m , 3.2×10^3 ; E. Gehreke and O. Reichenheim, for lithium, $V = 2.7 \times 10^7$ cms. per sec., and $e/m = 1.15 \times 10^3$; for sodium, $V = 1.8 \times 10^7$ cms. per sec., and $e/m = 0.41 \times 10^3$; and for strontium, $V = 1.1 \times 10^7$ cms. per sec., and $e/m = 0.21 \times 10^3$. For electrolytic hydrogen, $e/m = 9.5 \times 10^3$. Hence, the ratio

$$\frac{m_{\text{Li}}}{m_{\text{H}}} = 8.3; \quad \frac{m_{\text{Na}}}{m_{\text{H}}} = 23; \quad \frac{m_{\text{Sr}}}{m_{\text{H}}} = 90$$

showing that the masses of the positive ions are nearly equal to their at. wt. J. J. Thomson, W. Hammer, etc., have also evaluated the ratio e/m for these rays. Remembering that, so far as we can tell, all electrons are the same, and have a mass 1840 times less than that of the hydrogen atom, while the mass of the positively charged particles depends upon the nature of the gas, and is virtually the same as that of the atom from which it is derived, it is probable that **when a gas is ionized, one or more negatively electrified particles—electrons—are expelled from the atom, and the corresponding positively charged nucleus remains.**

E. Goldstein said that the spectrum of the positive rays is the same as the spectrum of the gas in the discharge tube. J. Stark found that the spectral lines of the positive rays in hydrogen are displaced towards the violet end when the rays are observed moving towards the spectroscope; and towards the red end when the rays are receding from the spectroscope. J. Stark, W. Hermann and S. Kinoshita, obtained similar results with nitrogen and mercury; J. Stark and K. Siegl, with sodium and potassium vapours; K. Siegl, F. Paschen, and J. Stark, with oxygen; J. Stark, with aluminium; S. Kinoshita, with carbon; H. Rau, and E. Dorn, with helium; and E. Dorn, with argon. H. Wilsar, J. Stark and W. Hermann, and G. S. Fulcher studied the spectra of the positive rays. The spectra obtained when the positive rays strike alkali salts show the characteristic lines of the metal, and these lines are more readily excited in the salts than in the metals themselves. The subject has been studied by V. Carlheim-Gyllensköld, and J. Stark and G. Wendt. The results by the latter are indicated in Table VI, and the last column shows the critical energy which is required to develop the spectrum of the metal.

TABLE VI.—THE EFFECT OF POSITIVE RAYS ON DIFFERENT COMPOUNDS.

Salt.	Light.		Critical energy in volts.
	Colour.	Wave-length λ .	
Lithium chloride	red	—	600
Lithium oxide	red	6710	600
Sodium chloride	yellow	—	750
Potassium chloride and oxide	—	580	<2400
Rubidium suboxide	—	572	<3500
Cæsium chloride	—	566	<4500
Magnesium chloride	—	518	<1200
Calcium fluoride	reddish-violet	—	1150
Calcium carbonate	—	—	1500
Calcium sulphate	"	—	1500
Calcium oxide	"	—	1400
Strontium chloride	—	496	<2500
Barium chloride	—	554-493	<2500
Thallium sulphate	—	535	4500
Zinc oxide	—	475	<4600
Aluminium oxide	—	396	<4500

If a mixture of different kinds of electrified particles travelling at a high velocity in one thin stream be passed simultaneously through electric and magnetic fields disposed at right angles to one another, the different kinds of particles are sorted into a number of smaller separate streams. The various streams can be demonstrated by causing them to impinge upon a fluorescent screen of, say, willemite, or on suitable photographic plates.

An idea of the apparatus employed can be obtained from Fig. 15. *A* represents the discharge tube, about 30 cms. in diameter, containing the gas under a low press. The anode is placed in a side tube, and the cathode *C* is placed in the neck of the flask. The cathode is an aluminium rod pierced with a narrow copper tube about 8 cms. long, and less than $\frac{1}{16}$ th cm. in diameter. To protect the tube from stray magnetic fields which might cause the particles to impinge on the walls of the tube and so be lost, the copper tube is enclosed for most of its length in a thick iron tube, and iron screens *VW* protect the main discharge from the influence of the magnet. To cool the various wax joints they are surrounded with a water-jacket *J*, this prevents the wax being melted when the cathode becomes hot. The rays pass between *LM*, which consists of two soft-iron blocks which are continuations with the pole pieces *PQ* of an electromagnet, from which they are electrically insulated by mica plates. This insulation enables the soft-iron blocks *LM* to be charged electrostatically. In this way, the positive particles are simultaneously subjected to continuous electric and magnetic fields. After passing these fields, the rays pass into *F* and fall either on a photographic plate or a glass plate covered with powdered willemite. F. W. Aston has introduced many improvements conducing to greater precision.

When the positive rays pass the electric and magnetic field they will be acted upon by forces Xe and He , where X denotes the strength of the electric field and H that of the magnetic field; e denotes the charge on each particle, and v their velocity. These forces cause the particle which strikes the photographic plate to be deflected through a distance kHe/mv in the case of the magnetic field, and k_eXe/mv^2 in the case of the electric field— m denotes the mass of the particle, and k_1 and k_2 are constants dependent on the dimensions of the apparatus. The fields are so disposed that the two deflections are at right angles to one another. *O*, Fig. 16, represents the position on the plate when the undeflected ray will

FIG. 15.—J. J. Thomson's Positive Ray Apparatus.

strike; OX and OY respectively denote the directions of the electric and magnetic deflections which deflect the particle to some point, say P . Then

$$\text{Electric deflection } PK = x = k_2 \frac{Xe}{mv^2}; \text{ Magnetic deflection } = PJ = y = \frac{He}{mv}$$

so that

$$\frac{y}{x} = \left(\frac{k_1 H}{k_2 X} \right) v; \quad \frac{y^2}{x} = \left(\frac{k^2 H^2}{k_2 X} \right) \frac{m}{e}$$

FIG. 16.

If the strengths of the two fields are kept constant, the quantities in brackets are also constant, and y/x will measure the velocity, and y^2/x , the ratio of the mass to the charge. If all the particles were identical and had the same velocity, the spot O would be shifted to P ; but the velocities of the particles are not all the same; and the rays are therefore drawn out into a line or band OFQ ; and all the particles for which m/e is constant will lie on the same parabolic curve $y^2 = ax$. If the particles have different at. masses, they will be sorted out into a series of parabolas OQ_1, OQ_2, \dots . Since the velocity y/x cannot exceed a certain limiting value, these curves will stop short at some definite distance from the OY axis. The curves can be measured and y/x and y^2/x evaluated. If the field is reversed during the exposure, the deflections are reversed, and symmetrical parabolic curves OQ'_1, OQ'_2, \dots are produced in the XOY' quadrant.

J. J. Thomson calls the series of small streams obtained from the original stream, the **electric spectrum of the atoms**, for the stream of electrified atoms is separated by this treatment into sub-streams—much as a beam of light from an illuminating gas is analyzed into different rays by passing through the prism of a spectroscope. From the displacement of the path of the stream of electrified particles under the influence of electric and magnetic forces of known intensity, J. J. Thomson has developed what he calls **positive-ray analysis**; this furnishes evidence on such subjects as:

Are the atoms of an element all alike?—The particles in any one stream are presumably all of the same kind because the parabolic curves are sharply divided, and show no tendency to merge one into another. If it were otherwise the curves would be “fuzzy.” Ordinary chemical analysis cannot decide whether particles of one kind of substance have all the same mass, because it can deal only with the average masses of billions of particles. J. J. Thomson found unknown lines indicating that the gas which has been called **neon** is probably a mixture of two different gases of at. wt. 20 and 22—but with a preponderating amount of the former. F. W. Aston, and A. G. Dempster have followed up J. J. Thomson’s positive ray method of analysis, and found that many elements can be resolved into two or more isotopic forms, which have so nearly the same at. wt., and so similar properties that they cannot be separated by known processes.

*Hydrogen, helium, nitrogen, oxygen, carbon, sodium, arsenic, phosphorus, and fluorine do not show any isotopic forms; boron (10 and 11), lithium (6 and 7), potassium (39 and 41), cesium (85 and 87), neon (20 and 22), argon (36 and 40), sulphur (32 and ?), chlorine (35 and 37), and bromine (79 and 81) have two isotopic forms with the respective at. wt. indicated in brackets; magnesium (24, 25, and 26); and silicon (28, 29, and possibly 30) have three isotopic forms; krypton has six isotopic forms with at. wt. 78, 80, 82, 83, 84, and 86; while xenon and mercury have many isotopes, but the at. wt. of the different forms have not been determined. The subject of isotopes has been considered by J. J. Thomson, F. A. Lindemann, F. Soddy, F. W. Aston, and T. R. Merton. There is also F. W. Aston’s review, *Isotopes* (London, 1922). The isotopes in the radium-uranium family are considered later.*

Atoms and molecules with multiple charges.—Any given gas furnishes a number of different curves showing the presence of positive ions with multiple charges. Thus, with oxygen, in addition to (1) ordinary neutral molecules, O_2 ; and (2) neutral atoms, O ; effects were obtained corresponding with streams (3) of atoms with one positive charge, O^+ ; (4) of atoms with two positive charges, O^{++} ; (5) of atoms with one negative charge, O^- ; (6) of molecules with one positive charge, O_2^+ ; (7) ozone

with one positive charge, O_3^+ ; and (8) molecules O_6 with a positive charge, O_6^+ . With hydrogen, evidence of entities H , H_2 , H^+ , H^- , and H_2^+ was obtained. T. R. Wilkins estimated that in air, out of 350 positive ions in air, only 3 per cent. were doubly charged; with helium, 10 per cent. were doubly charged; and with hydrogen, 0.5 per cent.

Intermediate stages of chemical action.—The photographic plate registers the rays within a millionth of a second after their formation, so that if a chemical reaction were taking place in the tube, it is possible that the method would disclose the existence of transient intermediate compounds as well as the final products of the reaction. For example, with *methane*, CH_4 , five lines occur corresponding with particles having masses 12, 13, 14, 15, and 16. These must correspond with particles having the composition, C , CH , CH_2 , CH_3 , and CH_4 . *Phosgene*, $COCl_2$, furnishes lines corresponding with particles having masses 99, 28, and 35.5, hence the decomposition proceeds by a separation of chlorine atoms from carbon monoxide without rupture of the carbon and oxygen atoms. No signs of a molecule NO_3 were observed during the oxidation of nitric oxide, NO , by oxygen.

Atomic weights.—The parabolic tracks recorded on the photographic plates enable the at. wt. of a gaseous substance to be determined within one per cent. of its true value without requiring more than 0.00001 gm. of the substance. The result, moreover, is not dependent upon the purity of the material, for impurities merely produce additional lines in the positive ray spectrum, and do not affect the curves produced by the substance under examination. The gases evolved from platinum by cathodic bombardment contained H^+ , H_2^+ , C^+ , O^+ , Ne^+ , O_2^+ , and an unrecognized element.

New elements.—If a spectroscopist observed an unknown line in the spectrum of a discharge tube, he would infer the existence of an unknown substance provided the line were not produced by some alteration in the condition of the discharge; similarly, if a new curve be obtained in the positive ray spectrum, the probable existence of a new element would be inferred. Thus, atm. nitrogen gives a curve corresponding with a substance having an at. wt. 40 times that of a hydrogen atom, and is not indicated on the plate when chemically prepared nitrogen is employed. The positive ray method, too, is far more delicate than spectrum analysis, for it enables a foreign gas to be detected in quantities too minute to be revealed by the spectroscope.

Allotropic hydrogen.—J. J. Thomson finds that a gas with at. wt. 3 is given off by most solids when bombarded by the cathode rays. It is interesting to remember that D. I. Mendeléeff (1871) predicted a new element of the halogen group with an at. wt. 3, but J. J. Thomson thinks that the gas in question is a triatomic molecule of hydrogen, H_3 , mainly because (1) deliquescent salts or salts containing combined hydrogen—e.g. KOH , $CaCl_2$, $LiOH$ —give continuous yields of the gas, while the supply with salts which do not contain combined hydrogen—e.g. LiI , Li_2CO_3 , KCl —is soon exhausted. (2) Attempts to obtain spectroscopic evidence of the new gas gave bright hydrogen lines with traces of mercury—derived from the apparatus used in manipulating the gas. (3) Vigorous sparking in the presence of oxygen, or contact with glowing copper oxide (or even exposure to bright light) destroys the gas. Assuming the gas is really H_3 , it is more stable than ozone, more stable indeed than any known allotropic form of an element. If hydrogen is univalent, it is difficult to reconcile its existence with the ordinary views about valency. J. J. Thomson explains it by assuming that the hydrogen atom with its positive nucleus and negative corpuscles exerts a force analogous with that exerted by a magnet; and a group of three atoms can arrange themselves about their axes to form a closed stable ring.

CHAPTER XXVI

RADIUM AND RADIOACTIVITY

§ 1. Becquerel Rays

The secret of all who make discoveries is to look upon nothing as impossible.—J. von LIEBIG.

ABOUT the time W. C. Röntgen¹ discovered the peculiar X-rays, radiating from phosphorescing Crookes' tubes, H. Becquerel repeated some experiments of A. Niépce de St. Victor in order to find "if the property of emitting very penetrative rays is intimately connected with phosphorescence." In other words, does the principle of reversibility apply? If Röntgen's rays make a fluorescent substance shine in the dark, will a fluorescing substance emit invisible penetrative rays? C. Henry, G. H. Niewenglowsky, and H. Becquerel found that insulated calcium sulphide can, in the dark, send out rays which pass through black paper, and fog a photographic plate; L. Troost, and W. Arnold made a similar observation with respect to zinc blende. H. Becquerel placed fragments of several uraniferous phosphorescent substances on photographic plates wrapped in two sheets of black paper. In about 24 hours, when the plates were developed, a silhouette of the phosphorescent substance appeared on the plate. Hence, it was inferred that "*the phosphorescent salts of uranium must emit radiations which are capable of passing through black paper opaque to ordinary light, and of reducing the silver salts of the photographic plate*, even when the uranium compound has been completely sheltered from the light." These conclusions were confirmed by J. Elster and H. Geitel, P. Spies, A. Miethe, G. C. Schmidt, and M. S. Curie. The radiations emitted by the phosphorescent substance are called **Becquerel rays**, though A. Niépce de St. Victor, thirty years previously, noticed that uranium salts could affect photographic plates in the dark, and G. le Bon called the radiations *lumière noire*, or black light. At first, H. Becquerel thought that these radiations were *lumière emmagasinée*—stored-up light—a kind of invisible phosphorescence; and he inferred that the radiations were identical with light rays in that they could be refracted, reflected, and polarized. The alleged facts were afterwards shown to be wrong, and the inference fallacious.

A substance which possesses the property of emitting these penetrative rays is said to be radioactive, and the property itself is called **radioactivity**. All substances containing uranium are radioactive. The energy is not stored like light in a phosphorescent substance, because the property is no different whether insulated or non-insulated uranium be used; the energy does not come from the air, because it is not affected by confining the uranium in a vacuum. It is therefore probable that the uranium is slowly undergoing some spontaneous change as an effect of its internal energy. Radioactivity does not depend upon light or heat; the emission of the rays appears to be a permanent and abiding property of uranium and its compounds; and it is independent of temp. and of all known physical conditions. No sign of a diminution or increase of the property has been detected whether the substance be heated towards 2000° or cooled towards -200°. A. Piccard and G. Volkart showed that with a magnetic field of 83,000 gauss, no variation of the order 1 per 1000 could be detected. The same weight of uranium, no matter how combined, emits the same amount of radiation. *The chemical*

properties of the elements—excepting perhaps the helium family—can be modified and controlled by changes in the chemical and physical conditions; but radioactivity is independent of these conditions. Consequently, the assumption is made that **radioactivity is an infra-atomic property**, and is not the same type of phenomenon as an ordinary chemical reaction. If chemistry be confined to the study of phenomena with the atom as unit, radioactivity regarded as an infra-atomic phenomenon, is a kind of *meta-chemistry*.

G. C. Schmidt found that thorium is radioactive in the same sense that uranium is radioactive, and these two elements have the highest at. wt.—Th, 232; U, 238. The radioactivity of thorium is readily shown by flattening an ordinary new gas mantle on the sensitive side of a photographic plate, and leaving all in darkness for about a week. When the plate is developed in the usual way, a photograph of the flattened mantle will be produced. The mantle contains sufficient thorium, as oxide, to demonstrate the effect.

H. Becquerel also found that when uranium is brought near to a charged gold-leaf electroscope, the gold-leaf gradually collapses. The rate at which an electroscope is discharged is a measure of the efficiency of the specimen in emitting rays. The charged electroscope, indeed, is more sensitive than the photographic plate for detecting Becquerel rays. Air which has been in contact with uranium and its compounds, like air which has been exposed to Röntgen rays, will discharge an electroscope, for exposure to these radiations makes air a conductor. It will be shown later that Becquerel's rays are complex, for they include the so-called α -rays analogous with the canal rays; β -rays analogous with the cathode rays; and γ -rays analogous with X-rays. S. Meyer and K. Przibram studied the coloration and luminescence of kunzite, glass, quartz, etc., by Becquerel's rays.

As indicated in connection with the union of hydrogen and chlorine, J. J. Thomson² failed to detect any sign of ionization during this reaction; G. Kümmell reported evidence to the contrary, but M. le Blanc and M. Vollmer confirmed J. J. Thomson's observation. L. Bloch considers that it is doubtful if any ionization occurs during the reaction between ammonia and hydrogen chloride; and none was observed in the oxidation of nitrogen peroxide, of sulphur dioxide, and of sulphur; or in the union of hydrogen with sulphur. A. Pinkus and M. de Schulthess observed ionization during the reaction of nitric oxide with oxygen or with chlorine; the action of ozone on nitric oxide or nitrogen peroxide; and in the decomposition of ozone. The failure of M. Trautz and F. G. Henglein to detect ionization is attributed to unfavourable conditions of measurement. M. de Broglie and L. Brizard concluded that chemical action produces ionization only when accompanied by a physical reaction such as the passage of a gas through liquid μ , breaking of a crystalline surface, luminescence, etc. They state that there is no ionization in the case of reactions of the following classes: (1) Between gases in the cold; (2) double decomposition in liquids; (3) dry decomposition of amorphous substances at slightly elevated temp.; (4) rupture of an inactive surface by bubbling, while there is ionization in the following cases: (1) Gases prepared by wet way; (2) vigorous reactions by projection into water; (3) dry actions accompanied by the decrepitation of crystals; (4) oxidation of sodium by moist oxygen—feeble ionization; (5) reactions with incandescence, such as flames, or combustion of metals in oxygen or chlorine; (6) reactions with luminescence, such as the oxidation of phosphorus and of quinine sulphate.

In 1782, A. L. Lavoisier and P. S. de Laplace³ noted that when a cylinder of coal is burning, the cylinder is negatively electrified, and the ambient gas becomes positively electrified. C. S. M. Pouillet made a similar observation with respect to burning carbon, and burning hydrogen. A. L. Lavoisier and P. S. de Laplace also noted that the hydrogen liberated by the action of sulphuric acid on iron is positively electrified. The phenomenon has been investigated by J. Enright, and J. S. Townsend. There are several other strictly chemical reactions—hydration of quinine or cinchonine sulphate; ⁴ action of sodium amalgam or calcium carbide

on water; ⁵ oxidation of phosphorus; ⁶ the formation of oxygen by the action of manganese dioxide on hydrogen peroxide; ⁷ the formation of ozone; the action of water vapour, chlorine, the hydrogen halides, and carbonyl chloride on alloys or amalgams of the alkali metals results in the metal acquiring a positive charge and the ambient atm. becomes negatively charged; ⁸ in the explosion of a mixture of hydrogen and oxygen; ⁹ in the action of carbonyl chloride, chlorine, and water on potassium-sodium alloys; ¹⁰ etc.—which have the power of rendering the ambient air a conductor of electricity so that it can discharge a charged electroscope; and an attempt has been made to find if the two phenomena are related. The temp. at which hydrogen and oxygen begin to combine in contact with carbon or platinum is almost the same, within the limits of the errors of measurement, as that at which these elements begin to form negatively charged electrons. This, however, is not sufficient to justify a belief that there is a *causal nexus* between the two phenomena. The property exhibited by many chemical reactions of making the ambient air electrically conducting must be sharply distinguished from radioactivity.

E. Rutherford has emphasized the fact that the activity of radioactive bodies has these special characteristics: (1) It is spontaneous; (2) It is exhibited by all the compounds of the radioactive elements; (3) It is not altered by changes in the physical or chemical conditions of the element; (4) The reaction is exothermal, but the speed of the decomposition is not affected by any known external condition; the thermal value of the reaction, too, is more than a million times greater than that of any known chemical reaction; (5) The decomposition proceeds in a series of stages—consecutive reactions; (6) Helium is one ultimate product of the decomposition; (7) Three types of “radiant rays” are emitted at different stages of the decomposition, which may ionize the ambient air, produce luminescent effects, and induce chemical changes.

A. Schuster ¹¹ expressed the idea that usually when a physical property has been discovered in one element, it will be found to be shared in varying degrees by all the other elements; and consequently radioactivity may prove to be a common property of all matter. In that case, the so-called radioactive bodies may be distinguished from others—like iron in the case of magnetism—by the enormously exaggerated forms in which they possess the property. The apparently inactive metals may possess radioactivity, but to so small a degree, that our powers of observation are insufficient to detect it. M. S. Curie examined a number of substances to find if any other radioactive elements exist in addition to the uranium-radium family, and to the thorium and actinium families, and found that none have a radioactivity even $\frac{1}{100}$ th of that of uranium. J. J. Thomson reported that potassium and rubidium, in vacuo, emit electrons while in darkness. N. R. Campbell and A. Wood tried to find if radioactivity could be detected in other elements, and found that potassium and rubidium both emit β -rays, but no α -rays. The β -ray activity of potassium is not more than $\frac{1}{1000}$ th of that of uranium; and that of rubidium about $\frac{1}{10}$ th that of potassium. N. R. Campbell, M. Levin and R. Ruer, E. Henriot, W. W. Strong, H. Lachs, K. Bergwitz, H. Thirring, W. Biltz and E. Marcus, J. W. Woodrow, R. J. Strutt, E. Müller, L. Dunoyer and E. H. Büchner also found that the salts of these two elements emit feeble radiations which affect a photographic plate. The radioactivities of rubidium and potassium are atomic qualities. There is no evident reason why elements of such low at. wt. should exhibit radioactivity. The phenomenon has not been observed with sodium or caesium. Therefore, while between 30 and 40 radioactive bodies are assumed to exist, not half a dozen of these bodies have been isolated. The properties of those radioactive elements which have not been isolated have been deduced from their behaviour when mixed with large proportions of other known elements. J. C. McLennan and W. T. Kennedy showed that the radioactivity of potassium and rubidium is not due to the action of the γ -rays known to be present in the atm. J. Elster and H. Geitel, and J. Satterly found the quantity of radium in these elements too small to produce the given effect. No success has attended the

efforts of N. R. Campbell, J. Elster and H. Geitel, and E. Henriot to concentrate the active constituent from potassium. E. Rutherford added that the fact that α -rays are absent is taken to mean that the β -radiation cannot arise from the presence of a known β -ray product which is separated with the potassium; for no β -ray product of long period is known which is not transformed into an α -ray product. O. Hahn and M. Rothenbach estimate the half-life period of rubidium to be 10^{11} years, and that of potassium, 3 to 7 times more.

G. le Bon¹² repeatedly affirmed that radioactivity is a universal phenomenon. The atoms of simple bodies, said he, emit emanations of the same family as the cathode rays. H. Geitel, C. T. R. Wilson, R. J. Strutt, N. R. Campbell, J. C. McLennan and E. F. Burton, H. L. Cooke, C. S. Wright, J. Elster and H. Geitel, G. Hoffmann, etc., have studied the phenomenon. Radioactivity is detected by the action of matter on a charged electroscope. The ionization, said E. Rutherford, may be due to one or more of the following effects: (i) the presence of a small quantity of radium emanation mixed with the air; (ii) a superficial activity due to the exposure of the metal to the radioactive matter present in the atm.; (iii) the presence of traces of known types of radioactive matter throughout the volume of the metal; (iv) the escape of a radioactive emanation from the metal into the gas; and (v) the effect of the penetrating γ -rays which arise from the earth and atm. After discussing each of these effects, he concludes:

Considering the evidence as a whole, there does not seem to be any adequate proof that ordinary metals possess an intrinsic activity corresponding to the well-known radioactive elements. The very weak activity actually observed is in all probability to be ascribed to the presence of traces of radioactive matter as impurities.

G. Hoffmann came to a somewhat similar conclusion in attempting to decide if all the elements are radioactive. J. H. Vincent said that the radioactivity of ordinary elements cannot be detected because of the low velocities of the emitted particles.

It is difficult to communicate a charge of electricity to a gas under normal conditions. This is shown by the insulating properties of air screened from ultra-violet light, and other agents which act on the gas, making it a conductor of electricity. Myriads of gaseous molecules per second may bombard a charged metal plate and rebound without electrification. B. Franklin¹³ mentioned that the vapour rising from an electrified water is not itself electrified; and L. J. Blake, H. Pellat, H. Beggeroff, J. C. Beattie, L. Sohncke, and G. Schwalbe also found that the vapour arising from boiling mercury is not electrified, however strongly the liquid be electrified. As J. J. Thomson¹⁴ expressed it, "when an electrified liquid co-operates, the electrified particles are left behind, just as a salt in soln. is left behind on evaporation." Air, however, does become a conductor of electricity when exposed to various other influences, ultra-violet light, hot metals, certain chemical reactions—*vide supra*—etc. This subject is discussed in J. J. Thomson's *Conduction of Electricity through Gases* (Cambridge, 1903). Gases can be electrified by the splashing of liquids, so that the air in the vicinity of a waterfall, where the water falls upon rocks and breaks into spray, is electrified. P. Lenard showed that a positive charge goes to the water, and the air is negatively electrified. Lord Kelvin noted that air which has bubbled through water is negatively electrified. J. J. Nolan has discussed the ionization of air by splashing water. J. J. Thomson found that the effect produced by dil. soln. of some salts, etc., is very great; but H. Zwaardemaker and H. Zeehuisen found that purified water and most inorganic salt soln. give no charge to water spray.

C. du Fay,¹⁵ E. F. du Tour, and others knew in the eighteenth century that the air in the vicinity of hot metals becomes a conductor of electricity, and many observations have been made on the subject since that time. The subject has been discussed in O. W. Richardson's monograph *The Emission of Electricity from Hot Bodies* (London, 1916). It is shown that the number of electrons emitted per

unit area of surface increases rapidly with temp., $T^{\circ}\text{K.}$, according to the formula $i = aT^b e^{-b/T}$, where a and b are constants, and i denotes the current per unit area. The ratio e/m for the electrons emitted by hot bodies is the same as that obtained for the cathode rays. Early in the nineteenth century, A. Volta¹⁶ found that flames are conductors of electricity, but the results of many subsequent observers are obscured by the conductivity induced by incandescent wires. The conductivity of gases containing salt vapours, and the flow of electricity through salt-laden flames, has been investigated by S. Arrhenius,¹⁷ etc. H. A. Wilson found that, under similar conditions with respect to temp., potential difference, and conc., the conductivity imparted to the flame by caesium, rubidium, potassium, sodium, lithium, and hydrogen chlorides or nitrates decreased in the order named. The subject is discussed in H. A. Wilson's *The Electrical Properties of Flames and of Incandescent Solids* (London, 1912). H. Hertz's discovery¹⁸ that the incidence of ultra-violet light on the spark gap facilitated the passage of the spark, was immediately followed by numerous investigations of the action of light, and of ultra-violet rays on the discharge of electricity from charged bodies—*vide* photochemical effect. The subject is discussed in the monographs, A. L. Hughes, *Photoelectricity* (Cambridge, 1914), and H. S. Allen, *Photoelectricity* (London, 1913). W. C. Röntgen¹⁹ noted the ionization produced in gaseous media by X-rays. J. S. Townsend²⁰ has shown that gases may be ionized by the collision of the molecules with fast-moving positive or negative ions. The subject is discussed in his monograph, *The Theory of Ionization of Gases by Collision* (London, 1910); and also by B. Bianu, P. O. Pedersen, and J. Franck and co-workers. The ionization of gases by Becquerel's rays from radioactive uranium, etc., has been studied by H. Becquerel,²¹ etc. The subject of radioactivity is discussed in the monographs, M. S. Curie, *Traité de radioactivité* (Paris, 1910); E. Rutherford, *Radioactive Substances and their Radiations* (Cambridge, 1913); S. Meyer and E. von Schweidler, *Radioaktivität* (Leipzig, 1916); F. Henrich, *Chemie und chemische Technologie radioaktiver Stoffe* (Berlin, 1918); W. H. Bragg, *Studies in Radioactivity* (London, 1912); F. Soddy, *The Chemistry of the Radioclements* (London, 1911-4).

§ 2. Radium

It is the glory of God to conceal a thing, but the glory of a king to search it out.—
SOLOMON.

For even the things which be in our hands—
These, knowing, we know not—so far from us,
In doubtful dimness, gleams the star of truth.

ANON.

Is the radioactivity of uranium due to the presence of an impurity?—
In 1898, P. and M. S. Curie,¹ and G. Bémont found that the radioactivity is due to the presence of *une nouvelle substance fortement radioactive, contenue dans la pechblende*; and in her thesis: *Recherches sur les substances radioactives* (Paris, 1903), Marya Sklodowska Curie examined the radioactivity of a number of uranium minerals and other substances. She found the following relative radioactivities, expressed in units $\times 10^{-11}$ ampères:

	Units.		Units.
Pitchblende (Johanngeorgenstadt)	8.3	Ammonium uranite	1.3
Pitchblende (Joachimstahl)	7.0	Sodium uranate	1.2
Pitchblende (Przibram)	6.5	Uranyl sulphide	1.2
Carnotite	6.2	Samarskite	1.1
Chalcolite	5.2	Uranyl sulphate	0.7
Autunite	2.7	Potassium uranyl sulphate	0.7
Metallic uranium	2.3	Aeschnyite	0.7
Orangite	2.0	Uranium nitrate	0.7
Uranium oxide (green)	1.8	Monazite	0.5
Pitchblende (Cornish)	1.6	Fergusonite	0.4
Uranic acid	1.6	Niobite	0.3
Thorium oxide	0.14	Xenotime	0.03
Cleveite	1.4	Tantalite	0.02

Obviously some uraniferous minerals are more active than uranium itself. Hence, it was inferred that "the strong activity of the pitchblende from Joachimstahl (Bohemia) is due to the presence of small quantities of a substance wonderfully radioactive, and different from uranium or any other simple body known." This result was confirmed by the extraction of the chloride of what was supposed to be a new element designated **radium**, Ra. The salt was over a million times more radioactive than uranium.

In its general chemical behaviour, radium resembles barium, and the first stage of the extraction of radium from its ores resembles the process which would be employed if barium was to be extracted. In the extraction, polonium accumulates with the bismuth and actinium with the rare earths. The separation of radium from pitchblende is conducted in three stages: (i) The separation of uranium from the ore; (ii) the extraction of a mixture of radium and barium bromides or chlorides from the residue; and (iii) the separation of the two chlorides by fractional crystallization—the radium salt has the lower solubility, and if a sat. soln. of the mixed chlorides is raised to boiling, and allowed to cool, the small part which crystallizes out is five times more radioactive than the part remaining in soln.

The chief mineral employed for the extraction of radium is pitchblende, which is found in commercial quantities in Bohemia, South Saxony, Cornwall, Gilpin County (Cal.), etc. The minerals uranite, samarskite, and brannerite rarely occur in commercial quantities. By weathering, they furnish autunite, torbernite, carnotite, and tyuyamunite. The two latter are the most abundant and furnish the bulk of the world's supply. They are found in S.-W. Colorado and S.-E. Utah; smaller quantities of carnotite occur near Olary (S. Australia). Tyuyamunite occurs in Tyua-Myun (Russian Turkestan). R. M. Kehny, C. H. Viol, and H. Foley have discussed the production and uses of radium. One ton of pitchblende, containing about 0.37 grm. of radium, furnished about half of this amount by the following method of extraction.

The powdered mineral is first roasted with sodium carbonate, and the product washed with warm water to remove the excess of sodium carbonate, and then with dil. sulphuric acid. The uranium passes into soln., and the insoluble residue contains sulphates of radium, calcium, lead, barium, etc., silica, and a small proportion of copper, zinc, aluminium, thallium, the rare earths, arsenic, antimony, bismuth, vanadium, tantalum, columbium, manganese, iron, cobalt, nickel, etc. The residue is $1\frac{1}{2}$ to $4\frac{1}{2}$ times as radioactive as metallic uranium. 10,000 kgrms. of pitchblende ore yield 3000 kilogrms. of residue.

In M. S. Curie's system, which includes A. Debiere's suggestions, the residue is treated by the following process: Radium sulphate is the least soluble sulphate in the residue, and to dissolve it, the sulphuric acid should be as far as possible removed. The residue is accordingly boiled with a conc. soln. of sodium hydroxide, and washed. Sodium sulphate, and lead, silica, and alumina are removed with the alkaline soln., and the washing. The insoluble residue is digested with hydrochloric acid; the material is disintegrated and most of it is dissolved. Polonium may be obtained by precipitation with hydrogen sulphide, and the filtrate, oxidized with chlorine, and treated with ammonia, gives a precipitate containing actinium. The barium and radium remain as undecomposed sulphates in the portion not dissolved by hydrochloric acid. The insoluble matter is washed and then boiled with a soln. of sodium carbonate; the barium and radium sulphates are transformed into carbonates. The washed residue is treated with dil. hydrochloric acid free from

sulphuric acid. The filtered soln. contains barium, radium, and some polonium, and actinium; it is treated with sulphuric acid when a mixture of sulphates of barium, radium, calcium, lead, and iron, with a trace of actinium, is precipitated; the filtrate contains a little actinium and polonium, which can be recovered as before. A ton of residue gives between 10 and 20 kgrms. of crude sulphate with a radioactivity about 60 times that of metallic uranium.

The crude sulphates are purified by boiling with a soln. of sodium carbonate, and the resulting carbonates dissolved in dil. hydrochloric acid. As before the soln. is treated with hydrogen sulphide for polonium; oxidized with chlorine, and treated with ammonia for actinium. The filtrate is precipitated with sodium carbonate; and the washed carbonates again converted into chlorides by treatment with dil. hydrochloric acid. The soln. is evaporated to dryness, and washed with conc. hydrochloric acid. Nearly all the calcium chloride dissolves while the barium and radium chlorides remain ready for fractionation. A ton of residue gives about 8 kgrms. of the mixed chlorides, whose radioactivity is about 60 times that of metallic uranium. The mixed chlorides are dissolved in water, the soln. boiled, and allowed to cool. The crystals, *C*, which separate are more active than those obtained by evaporating the mother liquid, *S*. The operation is then repeated with each portion *C* and *S*. This gives four portions. The less active fraction of *C* is added to the more active portion of *S*. The operation is now repeated with the resulting three portions. The scheme is shown diagrammatically in Fig. 1. After each series of operations, the sat. soln. arising from one fraction is added to the crystals arising from the following fraction; but if after one of the series the most soluble fraction has been withdrawn, then, after the following series, a new fraction is made from the most soluble portion, and the crystals of the most active portion are withdrawn. By the successive alternation of these two processes, an extremely regular system of fractionation is obtained, in which the number of fractions and the activity of each remains constant, each being about five times as active as the subsequent one, and in which, on the one hand, an almost inactive product is removed, whilst, on the other, is obtained a chloride rich in radium. The amount of material contained in these fractions gradually diminishes, becoming less as the activity increases. The number of portions is not allowed to increase indefinitely. The activity of the most soluble portion diminishes as the number increases. When its activity becomes inconsiderable, it is withdrawn from the fractionation. When the desired number of fractions has been obtained, fractionation of the least soluble portion (the richest in radium) is stopped, and it is withdrawn from the remainder. At first, six fractions were used, and the activity of the chloride obtained at the end was only one-tenth of that of uranium. When most of the inactive matter has been removed, and the fractions have become small, one fraction is removed from the one end, and another is added to the other end, consisting of the active chloride previously removed. A chloride richer in radium than the preceding is thus obtained. This system is continued until the crystals obtained are pure radium chloride. If the fractionation has been thoroughly carried out, scarcely any trace of the intermediate products remains. At an advanced stage of the re-fractionation, when the quantity of material in each fraction is small, the separation by crystallization is less efficacious, the cooling being too rapid and the volume of the soln. to be decanted too small. It is then advisable to add water containing a known quantity of hydrochloric acid; this quantity may be increased as the fractionation proceeds. The advantage gained thus consists in increasing the quantity of the soln., the solubility of the chlorides being less in water acidified with hydrochloric acid than in pure water. By using water containing much acid, excellent separations are effected, and it is only necessary to work with three or four fractions.

The crystals, which form in very acid soln., are elongated needles, those of barium chloride having exactly the same appearance as those of radium chloride. Both show double refraction. Crystals of barium chloride containing radium are colourless, but when the proportion of radium becomes greater, they have a yellow coloration after some hours, verging on orange, and sometimes a beautiful pink. This colour disappears in soln. Crystals of pure radium chloride are not coloured, so that the coloration appears to be due to the mixture of radium and barium. The maximum coloration is obtained for a certain degree of radium present, and this fact serves to check the progress of the fractionation. The fractional precipitation of an aq. soln. of barium chloride by alcohol also leads to the isolation of radium chloride, which is the first to precipitate. This method, which was first employed, was finally abandoned for the one just described, which proceeds with more regularity.

FIG. 1.—Scheme of Fractional Crystallization of Radium and Barium Chlorides.

M. S. Curie, however, occasionally made use of precipitation by alcohol to purify radium chloride which contains traces of barium chloride. The latter remains in the slightly aq. alcoholic soln., and can thus be removed. F. Giesel and H. Paweck recommended the separation of barium and radium by fractional crystallization in water from a mixture of the bromides. This method is advantageous, especially in the first stages of the fractionation. C. E. Scholl also obtained good results with the bromides. For the isotopic mesothorium *vide* thorium.

Many modified proposals have been made of the method of extraction employed by M. S. Curie. These different methods of treating radium ores can be classed: (i) Leaching the ore with sulphuric acid (H. Fleck, W. G. Haldane, and E. L. White; and H. N. McCoy); hydrochloric acid, or nitric acid (C. L. Parsons and co-workers, R. B. Moore and K. L. Kithil, and G. A. Koenig); (ii) Leaching the ore first with an alkali, and then with an acid—*e.g.* J. H. Haynes and W. D. Engle, H. M. Plum, and W. F. Bleeker digested the ore with a soln. of sodium carbonate, and digested the residue with dil. hydrochloric or nitric acid; L. Haitinger and C. Ulrich extracted pitchblende with alkali-lye and then dissolved it in dil. sulphuric acid; and (iii) Fusing the ore with some material which will open the ore—*e.g.*, W. F. Bleeker roasted the ore with sodium chloride and hydroxide; S. Radcliff fused the ore with sodium hydrosulphate; F. Ulzer and R. Sommer also used an alkali hydrosulphate; and E. Ebler roasted the material with lime or calcium carbonate and sodium and calcium chloride. E. Ebler and A. J. van Rhyn extracted more than 80 per cent. of the radium as crude sulphate, from earths poor in radium, by the following process:

The powdered mineral is mixed with about an equal weight of sodium or calcium chloride and calcium carbonate, and heated at the sintering temp. (800° – 1000°) for five or six hours in a muffle furnace. The cooled mass is powdered and extracted with dil. hydrochloric acid containing sulphuric acid and barium chloride. The sulphate precipitate containing the radioactive material can then be readily washed away from the coarse inactive particles and filtered off. The weight of crude sulphates obtained is about 7 per cent. of the original ore. This method was used to extract radium from Portuguese torbernite ore containing only 4.5×10^{-7} per cent., from Colorado carnotite sandstone containing 5.0×10^{-7} per cent., and from Mexican pitchblende-quartzite containing 2.84×10^{-7} per cent. of radium.

In R. B. Moore and K. L. Kithil's nitric acid process for extracting radium from carnotite, the powdered ore is heated with nitric acid and the insoluble residue discarded. H. D. d'Aguiar has described this process. The nitric acid soln. is treated with sulphuric acid when radium and barium sulphates are precipitated, while the vanadium and uranium salts remain in soln. The sulphates are reduced to sulphides, converted into chlorides, and fractionally crystallized.

W. Marckwald found that on adding a conc. aq. soln. of a mixture of radium and barium chlorides to a one per cent. sodium amalgam, part of the sodium in the amalgam is displaced by an eq. quantity of radium and barium, the proportion of radium absorbed being greater than that of barium; on decomposing the amalgam with hydrochloric acid, the metallic chloride obtained is much more active than the original salt. By repeating this process, a much enriched salt is obtained, but the manipulation is tedious, and the method offers little advantage over the ordinary one of fractional crystallization. Instead of converting the sulphates to chlorides by the tedious process of A. Debierne and M. S. Curie, it is advantageous, in many cases, to reduce the sulphates to sulphides and dissolve the latter in hydrochloric acid; thus E. Ebler reduced with calcium carbide: $\text{MSO}_4 + 4\text{CaC}_2 = 4\text{CaO} + \text{MS} + 8\text{C}$; and E. Ebler and M. Fellner, with calcium hydride: $\text{MSO}_4 + 4\text{CaH}_2 = 4\text{CaO} + \text{MS} + 4\text{H}_2$; C. L. Parsons and co-workers tried reducing with carbon: $\text{MSO}_4 + 4\text{C} = \text{MS} + 4\text{CO}$; F. Soddy, and C. L. Parsons also suggested coal gas; and F. Soddy, water gas. E. Ebler and W. Bender compared the different processes and obtained better results with the strongest reducing agent. O. Hönigschmid heated the sulphate in a mixed vapour of carbon tetrachloride and hydrogen chloride. According to C. L. Parsons and co-workers, the production of a precipitate, or the presence of one, in a radium-barium soln. does not necessarily involve the adsorption of

considerable quantities of radium from soln. As has already been pointed out, the precipitation of 700 grms. of lead sulphide in ammoniacal soln. carried with it only 3 out of 1,500 mgrms. of radium. The work of F. Paneth shows that any serious removal of radium by adsorption is likely to occur only when the radium forms an insoluble salt with the negative radical of the adsorbent. The failure of radium to be removed as sulphide, together with lead sulphide, accords well with its chemical nature, since radium sulphide is soluble. On the other hand, the completeness of its removal as carbonate, which is to be expected, has been shown by the fact that only 6.4 out of 1500 mgrms. of radium passed into 300 litres of filtrate. Even if barium sulphate is present or is precipitated in a soln. containing radium, the amount of radium removed is small provided a large excess of barium is present. F. E. E. Germann found that radium is adsorbed from soln. of its salts by barium sulphate, and the adsorption follows the laws of K. Kröcker, and H. Freundlich.

According to A. Coehn, radium is not deposited on a platinum electrode by the electrolysis of soln. in alcohol, acetone, or pyridine, since the cathode shows only a temporary induced activity. With aq. soln., cathodes of different metals acquire only a temporary radioactivity in presence of radium bromide soln.; a mercury cathode, however, becomes permanently active, and when extracted with hydrogen bromide gives a permanently active bromide. The difference of potential required for the separation of a metal (calculated from heats of formation) increases in the series calcium, strontium, and barium, but proceeds in the reverse direction when amalgams are produced, so that the separation of strontium on mercury requires 0.2 volt more than barium, and calcium 0.25 volt more than strontium; this difference is sufficient for the electrolytic separation of these metals. These values, however, are for soln., although the difference between radium and barium should be greater than between barium and strontium. It is not possible to separate these metals except with extraordinarily small current densities; metallic radium is, however, precipitated by barium amalgam. Neither barium nor radium can be separated from aq. soln. by deposition on melted Wood's alloy. Metallic radium cannot be satisfactorily deposited on amalgamated platinum; but can be deposited on amalgamated zinc, the upper part of the rod being protected from oxidation by means of paraffin wax. By precipitation on a pure mercury cathode and dissolution in hydrogen bromide, a considerable increase of activity is obtained in the bromide. A silver anode was used to absorb the bromine; and at first it showed a greater radioactivity than the cathode, but this was due only to an induced radioactivity, and disappeared at the end of 24 hours. The redissolving of the metallic radium in the soln. from which it is being deposited can be greatly checked by using methyl alcohol as the solvent in place of water. Metallic radium in the form of amalgam behaves like its compounds in that the radioactivity increases during several days to a maximum value.

M. S. Curie and A. Debierne prepared radium amalgam by the electrolysis of a soln. of 0.106 gm. of perfectly pure radium chloride with a cathode of mercury (10 grms.) and an anode of platinum-iridium. After electrolysis, the soln. contained 0.0085 gm. of the salt. The amalgam was quite fluid, whereas with barium under similar conditions, the amalgam is partly crystalline. The dried amalgam was transferred to an iron boat and heated cautiously in a quartz tube in a current of hydrogen purified by passage through the walls of a platinum tube heated in an electric furnace. The temp. of the boat was determined by a thermocouple. Most of the mercury was distilled at 270°. At 400° the amalgam became solid, and its m.p. rose progressively as the mercury was driven off to 700°. At this temp. no more mercury volatilized, but the radium itself commenced to volatilize and to attack the quartz tube energetically. The boat now contained a brilliant white metal. It adhered strongly to the iron, and blackened immediately on exposure to air, probably forming the nitride. The penetrating rays from the boat containing the metal, sealed in a glass tube, showed the normal increase follow-

ing the law of production of the emanation. E. Ebler and H. Herschfinkel obtained the more or less impure metal by heating the azide to 180° – 250° , when $\text{Ra}(\text{N}_3)_2 = \text{Ra} + 3\text{N}_2$.

§ 3. The Occurrence of Radioactive Substances

In 1902, J. J. Thomson ¹ found evidence of electronic activity in the air bubbled through the tap-water of Cambridge; and J. Elster and H. Geitel obtained similar results by drawing air through soils and clays; and the air of caverns was found to be more radioactive than normal atm. air. R. J. Strutt estimated the conc. of radium in a number of soils and rocks from widely different localities. The computation was based on an assumption as to the constant proportion of radium and uranium, which was afterwards shown to be erroneous. The results, corrected by A. S. Eve and D. McIntosh, showed that in 28 igneous rocks, the amount of radium ranges from 0.30×10^{-12} to 4.78×10^{-12} grms. per gram of material—the average is 1.7×10^{-12} . The highest values were obtained with granites, and the lowest with basalts and olivine rocks. For sedimentary rocks, the average of 17 determinations was 1.1×10^{-12} grms. per gram of material. J. Joly found the mean radium content of igneous rocks to be 5.5×10^{-12} , and of sedimentary rocks 4.3×10^{-12} grms. per gram.

Radium produces a radioactive gaseous emanation which itself gradually changes; if sufficient time be allowed and the mixture is in equilibrium, the amount of emanation is strictly proportional to the amount of the parent radium, so that given the amount of one, the amount of the other can be calculated. Other radioactive elements no doubt play their part, but radium so far preponderates that geochemical radioactivity is commonly stated in terms of radium. Comparative determinations can be made by spreading the dried powdered material over the same area on a plate introduced into the electroscope.² The subject has been discussed by S. C. Lind, P. Loisel, P. Ludewig, N. E. Dorsey, H. Greinacher, and O. Nürnberg. In estimating the amount of radium in rocks and minerals,

etc., the material is decomposed so as to bring it into soln. and enable the radioactive gas to be isolated. Its amount is then determined by its action on the air within an electroscope. The mineral is fused with sodium carbonate, or potassium hydroxide, and afterwards extracted with water, and the residue, if any, with dil. acid. If the mineral is directly soluble in a given menstruum, there is no need for the fusion process. The mixed soln. is stored for a few weeks in a closed flask, resembling *A*, Fig. 2, so as to allow the equilibrium amount of emanation to develop. To estimate the amount of radium, the flask *A* is attached to a water reflux condenser *B*; and the latter is connected with the rest of the apparatus, Fig. 2, by means of the ground-joint, *G*, held together by steel springs. The emanation is expelled from the flask by vigorously boiling for about an hour. The cooling water is run from the condenser *B*, to allow the steam to drive the emanation into the reservoir *C*. The stopcock is then closed. Meanwhile the air is exhausted from the electroscope by connecting the apparatus with the pump. The air in the

FIG. 2.—The Estimation of Radium in Minerals.

gas-holder *C*, charged with the emanation, is cautiously allowed to pass into the electroscope by opening the tap *F*. The rate at which the electroscope is discharged is measured by the number of scale-divisions the leaf of the electroscope falls per hour, and this is assumed to be proportional to the amount of radium in the original mineral. A mineral with a known amount of radium is employed as a standard of reference. The radium can also be computed from the amount of uranium—determined by analysis—in a sample of pitchblende ore, where the ratio uranium to radium is nearly constant, *viz.* one gram of uranium per 3.4×10^{-7} grms. of radium. Hence, therefore, the amount of uranium as well as of radium in a uraniferous mineral can be estimated by this method. In carnotite, and several other uranium minerals, the ratio of uranium to radium is not always constant and has to be determined by experiment.

EXAMPLE.—R. B. Moore and K. L. Kithil treated 22 mgrms. of a sample of pitchblende, known to contain the eq. of 50 per cent. of uranium; and, 3 hrs. after introducing the emanation to the electroscope, they found the leaf to fall 40.5 divisions per minute. The natural leakage of the instrument was 0.5 division per minute, so that the emanation from the radium in equilibrium with 0.01 gm. of uranium caused the leaf of the electroscope to fall 40 divisions per minute. Hence, a fall of one division per minute represents $0.01 \div 40 = 2.5 \times 10^{-4}$ grms. of uranium. This is the *constant of the electroscope*. One gram of a given pitchblende ore was fused with sodium carbonate, and at the end of a month, the soln. was treated as above described. In 3 hrs. the leaf of the electroscope fell at the rate of 18.5 divisions per minute. Allowing for the natural rate of the electroscope, the emanation produced a leakage of 18 divisions per minute. Hence, the ore contained $18 \times 2.5 \times 10^{-4} = 45 \times 10^{-4}$ grms. of uranium. The ratio of radium to uranium in pitchblende ores is approximately 3.4×10^{-7} grms. of radium per gram of uranium, one gram of the pitchblende in

question not only contains 45×10^{-4} grms. of uranium, but also $(45 \times 10^{-4}) \times (3.4 \times 10^{-7}) = 1.53 \times 10^{-9}$ grms. of radium.

Numerous observations have been made on the radioactivity of rocks and minerals.³ Expressing the results in billionths of a gram per gram of material. A. Holmes found :

		Grm. per gram.
Igneous rocks . . .	{ Acidic rocks	3.1×10^{-12}
	{ Intermediate rocks	2.1×10^{-12}
	{ Basic rocks	1.1×10^{-12}
	{ Ultrabasic rocks	0.5×10^{-12}
Sedimentary rocks . . .	{ Clays	1.5×10^{-12}
	{ Sandstones	1.4×10^{-12}
	{ Limestones	0.9×10^{-12}

The igneous rocks are therefore more radioactive than the sedimentary rocks. J. Joly considers it probable that the uranium is in considerable part removed during the general disintegration of the parent rock ; but the radioactivity of the detrital rocks shows that a proportion of the uranium is retained in the *débris* of the parent rock. Seventeen samples of deep-sea deposits from the *Challenger* expedition were radioactive. According to J. Joly :

Extent in sq. miles	Globigerina ooze. 49.5×10^6	Radiolarian ooze. 2.5×10^6	Red clay. 51.5×10^6
Calcium carbonate	92.24 64.34	10.19 3.89	28.28 12.00 per cent
Radium .	6.7×10^{-12} 7.4×10^{-12}	22.8×10^{-12} 50.3×10^{-12}	52.6×10^{-12} 15.4×10^{-12}

This shows that the radioactivity and the proportion of calcareous matters stand in an inverse order. The first red clay is exceptional in that the proportion of calcium carbonate is higher than usual ; J. Joly says that it is probable that the lower part of the deposit, richer in calcareous matter, dilutes the more recently formed clay above. J. Joly gives 6×10^{-12} grms. of radium per gram in the material spread on the ocean floor, and hence estimates that there are 11.7×10^6 tonnes of radium spread on the ocean floor.

No marked parallelism has been observed between the acidity of the rocks and their radioactivity. The radium is considered to be an accessory mineral, and different samples of the same kind of rock, even from the same locality, were found by H. Mache and M. Bamberger to give very different results ; and E. H. Büchner found that the radioactivity of the rocks can be better classified geographically than petrographically. From borings taken at different depths, A. S. Eve and D. McIntosh, E. H. Büchner, and H. E. Watson and G. Pal could find no simple relation between the radium content and depth ; nor is there any relation between the geological age and the radioactivity of igneous and sedimentary rocks. J. Joly estimated the radium content of the earth's crust to be $2.0-2.6 \times 10^{-12}$ grms. per gram. The uranium content is calculated on the assumption that 10^{-12} grms. of radium represent 3×10^{-6} of uranium. The radioactivity of the soil approximates 8×10^{-12} grms. of radium per c.c. J. Joly found the Vesuvian lavas contained 12.3×10^{-12} grms. of radium per gram. O. Scarpa also studied these lavas.

R. J. Strutt, G. A. Blanc, J. Joly, and H. Mache and M. Bamberger have discussed the radioactivity due to thorium ; and they conclude that the aggregate radioactivity from this source is not inconsiderable in comparison with that derived from the radium elements. From the estimate of J. Joly, J. H. J. Poole, and A. Holmes, the radioactive thorium in different rocks is as follows :

		Grm. per gram.
Igneous	{ Acidic rocks	2.33×10^{-6}
	{ Intermediate rocks	2.16×10^{-6}
	{ Basic rocks	0.79×10^{-6}
	{ Clays	1.25×10^{-6}
Sedimentary	{ Sandstones	0.55×10^{-6}
	{ Limestones and dolomites	$< 0.08 \times 10^{-6}$

The thorium content is rather greater, but of the same order of magnitude as the uranium content.

It is assumed that there is a genetic relation between uranium and radium—*vide infra*—and this is confirmed by the nearly constant ratio Ra : U, in very old compact and unweathered rocks where it may be assumed that the changes involved are in the steady state. According to J. H. L. Johnstone and B. B. Boltwood, the total activity of uranium in equilibrium with its products is 4.73 times the activity of uranium alone. R. J. Strutt,⁴ B. B. Boltwood, and H. N. McCoy found Ra : U = $3.4 \times 10^{-7} : 1$; A. Becker and P. Jannasch obtained 3.38×10^{-7} to $3.415 \times 10^{-7} : 1$; and F. Soddy and R. Pirret, $3.15 \times 10^{-7} : 1$; E. Gleditsch, $3.22 \times 10^{-7} : 1$; and S. C. Lind and L. D. Roberts give $3.40 (\pm 0.03) \times 10^{-7}$ —*vide* Table I. W. Marek-

TABLE I.—THE RADIUM-URANIUM RATIO OF SOME RADIOACTIVE MINERALS.

Minerals.	Locality.	Activity.	Radium per cent.	Uranium per cent.	Ratio Ra U
Chalcolite . .	Saxony . .	—	0.714×10^{-5}	39.29	1.82×10^{-7}
Carnotite . .	Colorado . .	0.76	0.375 "	16.00	2.34 "
Gummite . .	Germany . .	—	0.31 "	12.20	2.54 "
Autunite . .	Autun . .	1.52	1.20 "	46.92	2.56 "
Autunite . .	Tonquin . .	1.50	1.22 "	47.10	2.59 "
Chalcolite . .	Germany . .	1.20	0.905 "	28.80	3.14 "
Pitchblende . .	Joachimsthal . .	1.90	1.48 "	46.10	3.21 "
Gummite . .	Germany . .	1.23	0.58 "	17.37	3.34 "
Chalcolite . .	Portugal . .	1.70	1.30 "	39.03	3.33 "
Samarskite . .	India . .	0.42	0.295 "	8.80	3.35 "

Clévéite . .	" . .	2.96	1.81 "	54.00	3.32 "
Uranothorite . .	" . .	0.76	0.16 "	4.83	3.31 "
Fergusonite . .	" . .	0.30	0.223 "	6.30	3.55 "
Thorianite . .	Ceylon . .	2.32	0.66 "	18.60	3.55 "
Chalcolite . .	Cornwall . .	2.00	1.70 "	48.66	3.49 "
Pitchblende . .	" . .	1.40	1.07 "	28.70	3.74 "

wald and co-workers found with different samples of pitchblende containing 9.01 to 71.20 per cent. of uranium, and a ratio between 3.32×10^{-7} and $3.34 \times 10^{-7} : 1$ —mean $3.329 \times 10^{-7} : 1$; thus :

U per cent.	9.01	23.74	41.46	44.53	59.95	63.52	66.55	71.20
Ra/U $\times 10^7$	3.320	3.339	3.331	3.323	3.328	3.341	3.328	3.235

S. C. Lind and C. F. Whittemore found for carnotites from Colorado and Utah :

U per cent.	1.29	1.78	2.04	3.33	6.60	7.94	20.6	28.18
Ra/U $\times 10^7$	3.42	3.38	3.58	3.33	4.59	2.99	2.41	3.59

Differences may be anticipated with younger minerals which have not had time to accumulate the maximum value of radium; or with products which have been weathered and leached by water. Thus, J. Danne found a sample of pyromorphite which contained radium and no uranium; H. N. McCoy, however, showed that the radium is confined to a surface layer which had been deposited by flowing water. E. Gleditsch found the ratio with chalcolite to be 1.82×10^{-7} ; with carnotite, 2.34×10^{-7} ; and with autunite, 2.58×10^{-7} . A. S. Russell, and F. Soddy and R. Pirret, also obtained low results with autunite. The best representative value for the Ra : U ratio in uranium minerals is $3.3 \times 10^{-7} : 1$. Since the uranium content of U_3O_8 is 84.82 per cent., it may there be anticipated that an ore with 50 per cent. of U_3O_8 , will contain 1.4×10^{-7} grms. of radium per gram of ore; *i.e.* a gram of radium to nearly 7000 kgrms. of ore. There will be about 10–20 per cent. loss of radium in the extraction. The subject has also been investigated by L. Haitinger and C. Ulrich, H. Souczek, S. Meyer and V. F. Hess, A. Muguet and J. Scroin, etc.

From the fact that radioactive substances constantly emit heat, and since the emanations are ubiquitous in the earth's crust, it follows that the heating effects of these substances must play an important part in maintaining the heat of the earth, and must have profoundly modified the rate of cooling of the earth in past ages.⁵ Attempts have also been made by B. B. Boltwood,⁶ and A. Holmes to calculate the age of rocks and minerals from the ratio Pb/U, making certain assumptions as to the relations of the two elements; R. J. Strutt,⁷ and J. A. Gray dealt likewise with the helium and uranium or radium ratio; but A. Piutti showed that the ratio is too irregular to justify any calculations. The smaller circular spots, called *pleochroic haloes*, found in brown mica, e.g. biotite—in cordierite, and in some other minerals are assumed to be caused by the radioactive properties of a centrally placed mineral particle. They have been studied by O. Mügge, J. Joly and E. Rutherford;⁸ and they have been used in attempts to estimate the ages of the minerals in which they occur. J. Joly inferred from the peculiarities of some haloes in the Ytterby and Arendal micas that a new radioactive exists emitting an α -ray with a range of about one cm. in air; and he called this hypothetical element *hibernium* (Hibernia or Ireland).

The waters of the ocean and inland seas are radioactive. Estimates have been made by R. J. Strutt,⁹ A. S. Eve, J. Satterly, etc. J. Joly found for the waters of the Atlantic ocean from 0.007×10^{-12} to 0.038×10^{-12} grms. per c.c.; the Indian Ocean, 0.004×10^{-12} to 0.009×10^{-12} grms. per c.c.; the Arabian Sea, 0.027×10^{-12} grms. per c.c.; the Mediterranean Sea, 0.008×10^{-12} grms. per c.c.; and for the Black Sea, 0.007×10^{-12} grms. per c.c. The average of all 24 determinations is 0.017×10^{-12} grms. per c.c. J. Joly estimates that there are 20×10^9 grms., or about 20,000 tonnes of radium in the waters of the ocean—assumed to be 1.452×10^{-18} tonnes. The water from deep-seated springs and wells¹⁰ has usually a marked radioactivity, which is attributed by F. Himstedt to deep-seated radioactive minerals. It has been stated that the curative properties of certain mineral waters—e.g. those of Buxton, Bath, Wiesbaden, Bohemia, etc.—are due to their radioactivity. This statement is mere guessing, because so little is known about the physiological action of the radiations from radioactive materials.

In 1900, H. Geitel showed that one or more radioactive substances are everywhere present in the atm.,¹¹ and C. T. R. Wilson showed that an insulated electrified conductor gradually loses its charge even inside a closed vessel. E. Rutherford and H. L. Cooke, and J. C. McLennan and E. F. Burton found a penetrating radiation in the lower atm., presumably derived from radioactive substances near the surface of the earth. J. Elster and H. Geitel showed that a bare wire exposed to the atm. and negatively charged, gradually becomes coated with a radioactive deposit which H. A. Bumstead showed to consist of varying proportions of emanations derived from radium and thorium. They can be collected from atm. air, (i) by absorption on charcoal; (ii) by condensation at a temp. below -150° ; or (iii) by deposition on a conductor charged to a high negative potential. A. S. Eve estimated that an amount of emanation corresponding with 80×10^{-12} grms. radium per cubic metre of atm. air, and J. Satterly gave 100×10^{-12} grms. of radium per cubic metre. G. C. Ashman found the variations from day to day range from 45×10^{-12} to 200×10^{-12} grms. per cubic metre; A. S. Eve found the variation to be 1 to 7. Over the Pacific ocean and near the Antarctic ocean, the average amounts are respectively 3.3×10^{-12} and 0.4×10^{-12} grms. per cubic metre. Thus, the emanations are found more particularly in the atm. over land than over the sea. These emanations are more abundant in mines and cellars than in open air, and they are assumed to be derived by diffusion from the radioactive matters in the earth, and this is in agreement with the fact that the radioactivity of deep-sea water is greater near the bottom than near the surface. F. Henrich investigated the radioactivity of the gases from various springs—Gastein, Carlsbad, and Wiesbaden—and found them more radioactive than the spring water. The radioactivity of gases from thermal springs has been studied by P. Curie and A. Laborde, H. Mache, A. Herrmann and F. Pesendorfer, C. Moureu, etc. R. Nasini and co-workers, and E. Sarasin studied the radioactive gases from Tuscan suffioni; and J. Elster and H. Geitel, the gases from deep borings. In 1905, P. Langevin discovered the presence of a comparatively small number of slow-moving massive ions in the atm.; they are more abundant in towns

than in the open country. H. Kolhörster also found the existence of an extremely penetrating radiation in the atm. A part of this radiation is supposed to be derived from the earth because it decreases with elevation up to about 1·5 kilometres; but, from this level up to 9 kilometres, as far as it has been tested, the ionization increases very rapidly. It is therefore inferred that these penetrating radiations come from outside—apparently the sun.

C. T. R. Wilson¹² found that radioactive matter is carried down from the air by rain; and he isolated therefrom a radioactive preparation. The radioactivity of freshly fallen snow was established by S. J. Allen, J. C. McLennan, C. T. R. Wilson, H. A. Bumstead, A. Righi, G. Constanzo and C. Negro, etc., and a radioactive preparation isolated. According to J. Jaufmann, snow contains radium and thorium emanations. Ground-ice is also radioactive. F. Himstedt and J. C. McLennan, found fresh petroleum is very radioactive in virtue of a dissolved radioactive emanation; but that which has been distilled was found by E. F. Burton to be no longer radioactive. H. Mache and S. Meyer, G. Gehlhoff, and G. Severin and A. Hurmuzescu have studied the radioactivity of deposits and sediments from spring waters.

Cosmic particles found on the floor of the ocean have been examined by J. Joly¹³ to find if radium occurs in extra-terrestrial regions; but he found no marked evidence of radium therein. None of the well-defined spectral lines of radium has been identified in H. A. Rowland's measurements of the solar spectral lines. F. W. Dyson reported that there are a few indecisive lines in the spectrum of the solar chromosphere which might belong to radium. H. Giebler detected radium and its emanation in the spectrum of the star Nova geminorum 2; and M. B. Snyder also reported radium in the spectra of spiral nebulae and of star clusters. H. Bongards believes a radium emanation to be a minor component of the solar material rays.

§ 4. The Properties of Becquerel's Rays

The Becquerel rays from pitchblende have the same properties as the radiations from radium; they produce similar effects, but the latter act over a million times more intensely than the former. Radium radiations ionize the air through which they pass, and, as J. Elster and H. Geitel¹ have shown, the electrical discharge passes more freely through the ionized air; brush and spark discharges pass into a glow discharge. P. Curie,² A. Righi, H. Becquerel, G. Jaffé, C. Böhm-Wendt and E. von Schweidler, H. J. van der Bijl, T. Bialobjesky, H. Greinacher, J. C. McLennan and D. A. Keys, A. Zaroubine, etc., found that many liquid insulators acquire to a greater or less degree the power of conducting electricity when exposed to the influence of radium radiations; this is the case, for instance, with carbon disulphide, petroleum ether, carbon tetrachloride, benzene, liquid air, vaseline, amylene, paraffin, etc. B. Sabat found that the conductivity of highly purified water is not appreciably affected by β - and γ -rays; but F. Kohlrausch found the conductivity is augmented 0.01×10^{-6} times by the action of radium radiations. The ionization of solid dielectrics by Becquerel's rays was found by H. Becquerel, and demonstrated by A. Righi, T. Bialobjesky, B. Hodgson, W. Dietrich, A. Schaposchnikoff, and H. Greinacher. According to A. Becker, shellac, mica, and rubber become conducting under the influence of these rays; the conductivity of selenium was found by F. Himstedt, and E. Bloch to be augmented; B. Sabat, and R. Paillot found that the resistance of copper, iron, bismuth, platinum, steel, and brass is augmented by exposure to these rays, and it diminishes when the rays are removed. J. Trowbridge and W. Rollins detected no influence on aluminium. N. Hesebus studied the action of radium radiations on contact electricity; and N. Georgiewsky, on the speed of cooling of a hot body. J. J. Thomson found that, like cathode rays, and ultra-violet light, radium radiations in air sat. with moisture cause the condensation of water.

M. S. Curie³ found that preparations rich in radium salts glow with a faint blue **phosphorescence**; the greater the degree of purity of the preparation, the more intense the luminescence. W. Marckwald concluded that the luminescence decreases as the degree of purity increases; he said that highly purified radium bromide has but a feeble luminescence. *Au contraire*, O. Hönigschmid said that molten purified radium chloride or bromide luminesces so strongly that it can be seen in daylight as a faint violet-blue glow. S. Meyer and E. von Schweidler found that cooling to the temp. of liquid air has no influence on the luminescence. M. S. Curie observed that the colour of the phosphorescent light becomes more violet with the lapse of time. The luminescence does not always disappear immediately the source of the rays is removed. H. Rüchardt and G. Berndt observed the action of α -rays from radium on phosphorescent strontium bismuth phosphide. H. Herszfeld and L. Wertenstein studied the tracks of the α -particles which make a grazing impact on a zinc sulphide screen.

E. Marsden found the luminescence with a sample of **zinc blende**, exposed to radium radiations, attained a maximum after 20 minutes' exposure, and vanished rather more slowly when the exciter was removed; with **willemite** the maximum

is quickly attained and it likewise quickly vanishes. S. Meyer and K. Przibram observed the after-luminescence persisted for some hours with certain samples of **fluorspar**, **kunzite**, and **Iceland spar**. F. Giesel said that the action with anhydrous radium halide is decreased when water is present, but the intensity is restored when the preparations are dried. Soln. luminesce faintly, although it is difficult to distinguish between the luminescence of the soln. and of the walls of the containing vessel.

H. Becquerel, P. and M. S. Curie, F. Giesel, P. Bary, G. T. Beilby, J. Borgmann, etc., noted the intense luminescence produced by radium radiations on *adularia* (blue), *apatite* (green to orange), *barium cyanoplatinate* (green), *calcite* (rose), *cerussite* (blue), *coemanite* (blue), *diamonds* (blue), *fluorspar* (blue), *fowlerite* (blue), *greenockite* (blue), *Iceland spar* (rose), *kunzite* (red to orange), *magnesium cyanoplatinate*, *millerite* (green to orange), *native sulphur* (blue), *orthoclase* (blue), *pectolite* (orange), *quartz* (blue), *rhodonite* (blue), *rock-salt* (blue), *sapphire* (blue), *scheelite* (blue), *sparteite* (orange), *uranyl sulphate*, *willemitite*, *wollastonite* (orange), *zinc blende* (yellow), *zircon* (blue), etc. Less intense is the luminescence with *amblygonite*, *amethyst*, *analcime*, *anglesite*, *anhydrite*, *apophyllite*, *aragonite*, *autunite*, *barytes*, *beryllonite*, *bertrandite*, *brewsterite*, *brucite*, *capholite*, *castor*, *chabasite*, *coelestine*, *edlingtonite*, *gypsum*, *harmotome*, *heulandite*, *jamesonite*, *kainite*, *lanarkite*, *leadhillite*, *linarite*, *mimetesite*, *montebrasite*, *natrolite*, *opal*, *potash alum*, *prehnite*, *pyromorphite*, *quartz* (smoky), *ruby*, *scolecite*, *sericite*, *serpentine*, *sodium nitrate*, *spodumene*, *stilbite*, *strontianite*, *tourmaline*, *thenardite*, *witherite*, *zincite*, *zircon*. Among other luminescent substances are *salicylamide*, and *salicylates* of *zinc* and the *alkaline earths*; *salts* of *quinine*; *carbon disulphide*; *petroleum*, *glass*, *paper*, *gun-cotton*, *animal skin*, *blood*, *horn*, *nails*, *saliva*, etc.

W. and M. L. Huggins found that the weak phosphorescent light of radium showed the band spectrum of nitrogen. This has been traced to the action of the α -rays, either in free nitrogen close to the radium, or in the nitrogen occluded in the radium compound. The violent collisions of the α -particles from radium with the molecules of the gas in its path set up vibrations which give the characteristic spectrum of the gas. This unusual result, says E. Rutherford, is the first example of a gas giving a spectrum when cold, without the stimulus of a strong electric discharge. B. Walter and R. Pohl found that the atoms of nitrogen appear to be more easily stimulated than those of any other gas yet examined. F. Himstedt and G. Meyer give 3577, 3371, 3300, and 3159 for the wave-lengths of the lines in the spectrum. W. Crookes, and J. Dewar and P. Curie said that the spectrum is not observed if the luminescent radium salt is confined in an evacuated vessel. J. Stark, W. Marckwald and K. Hermann have also discussed this subject.

Native substances which exhibit **thermo-luminescence** lose this quality when they have been heated a long time, but the property is restored by exposure to radium radiations or to cathode X-rays. Thus, W. Trenkle restored marble and *apatite*; H. Becquerel, *fluorspar*; G. Kunz and C. Baskerville, *chlorophane*; and S. Meyer and K. Przibram, *kunzite*, *fluorspar*, and *Iceland spar*. Some substances which do not exhibit thermo-luminescence, acquire this quality after exposure to radium radiations—*e.g.* *browned glass*; and *quartz*. Various borates also show thermo-luminescence after exposure to radium radiations, or cathode rays.

Li	Na or Ba	Be	Mg	Sn	Zn or Zr	Ni	Cr or Mn
reddish-orange	green	orange-yellow	ruby-red	blue	white	rose	yellow

M. S. and P. Curie⁴ noted that when **glass** and **porcelain** are exposed to radium radiations, they are coloured violet or brown; the coloration depends on the composition; glass containing manganese appears violet. The discoloration persists after the source is removed, but if heated to 500°, the original colour is restored and the change is attended by thermo-luminescence. The action has been discussed by M. S. Curie, R. Lucas, W. Crookes, S. C. Lind, N. Georgiewsky, etc. *Didymium glass*, according to C. Baskerville, becomes *rose-coloured*. Many **minerals** are discoloured by exposure to radium radiations.

A. Miethe found numerous gem-stones are discoloured by radium radiations—*diamond*, *sapphire*, *emerald*, *chrysoberyl*, *topaz*, *tourmaline*, etc. Dark coloured *sapphires*, *ruby*,

and dark-coloured tourmalines are not changed. The action of radium radiations on different minerals and salts has been studied by E. Goldstein, F. Giesel, S. Skinner, W. Ackroyd, etc.—molten quartz becomes dark brown; rose quartz, smoky quartz, and citrine become dark brown; topaz becomes orange-yellow; amethyst, darker violet, sapphire, brownish-yellow; ruby, deeper in colour; Iceland spar, citron-yellow; and zircon, reddish-brown. Hiddenite and willemite are scarcely changed; kunzite becomes green; fluorspar, violet; bakelite, wine-red; barytes, blue; barium cyanoplatinate, yellowish-brown; zinc sulphide, yellow; hemimorphite, brownish-yellow; hyacinth, reddens; sulphur, greenish-yellow; rock-salt, blue; mercurous sulphate, brown; and potassium uranyl sulphate, yellow; etc. The action on some salts of the alkalis and alkaline earths is shown in Table II.

TABLE II.—ACTION OF RADIUM RADIATIONS ON SALTS OF THE ALKALIES AND ALKALINE EARTHS.

	Li	Na	K	Rb	Cs	Ca	Sr	Ba
Chloride .	violet to brown	yellow	purple	bluish-green	green	rose yellow	—	—
Bromide .	yellow to grey	lilac	sky blue	—	—	—	—	—

The theory of the discoloration of minerals by the action of radium radiations has been studied by J. Elster and H. Geitel, R. Abegg, F. Giesel, E. Wiedemann and G. C. Schmidt, E. Bose, etc.—*vide* 2. 20, 15. H. Siedentopf found that with the ultramicroscope, particles of sodium could be detected in discolored sodium chloride. F. Goldstein found the discoloration is more intense if the substance has been previously heated or melted. F. Giesel found the colours may be different if impurities are present. J. Elster and H. Geitel found that when the discoloration vanishes, the decolorized salt is photoelectric in daylight. N. Georgiewsky found that mica shows chromatic polarization changes which disappear with heat; while gypsum and Iceland spar change their optical properties but are not discoloured. N. Egoroff, and C. J. Salomonsen and G. Dreyer found colourless quartz becomes pleochroic. P. Lenard and S. Saeland, and S. Meyer and K. Przibram observed the photoelectric effect with discoloured kunzite, fluorspar, etc. W. Crookes found that the diamond is partially graphitized.

According to M. S. Curie,⁵ the effect of radium radiations on a photographic plate is similar to that of light. The **photographic action** has been studied by J. Petri, G. W. A. Kahlbaum, C. Bonacin, S. Skinner, U. Behn, H. Stroud, S. Kinoshita and H. Ikeuti, M. Reinganum, W. Michl, E. Rutherford and H. Geiger, E. Mühlestein, S. Meyer and F. Paneth, W. Makower and H. P. Walmsley, R. R. Sahni, F. Mayer, etc.

The formation of ozone by the action of α -rays outside a thin glass bulb containing some emanation, or in the neighbourhood of a conc. radium preparation, can be detected by its odour. F. Krüger also found ozone to be formed by cathode

rays. In either case the ozonization is considered to be an electrical process—in the former case by α -rays, in the latter by β -rays. R. A. Millikan and co-workers showed that the ionization of some common gases—*e.g.* oxygen—by α -rays results in the removal of one electron per mol. S. C. Lind assumed a cluster of ions are formed about a charged atom or molecule, which, on being electrically neutralized, would break down into the highest stable polymer—ozone in the case of oxygen. L. B. Loeb, and E. M. Wellisch doubt the formation of cluster-ions. The mechanism of the ozonization of oxygen has been discussed by W. W. Strong, and E. K. Rideal and J. Kunz; while the formation of triatomic hydrogen has been investigated by G. L. Wendt and R. S. Landauer. P. and S. Curie, and F. Giesel found that **air** and **oxygen** are ozonized by radium radiations. According to S. C. Lind, the radiations from a gram of radium form 0.72 gm. ozone per hour.

According to S. C. Lind, *the chemical activity of the α - or β -rays is to be attributed to their kinetic energy and ionizing power, not to their own charges, which, in comparison with the secondary charges produced, are wholly insignificant.* In nearly all the reactions brought about by the α -rays, there is an approximate statistical agreement between the number of ions generated, and the number of molecules acted upon. F. Giesel and G. Bodländer, and W. Ramsay and F. Soddy found that the **water** in which a radium salt is dissolved is decomposed, forming hydrogen and oxygen—and, according to W. Ramsay, the α -rays are the agent which evokes the decomposition. W. Ramsay and A. T. Cameron showed that the rate of the reaction is proportional to the quantity of emanation present; and that each atom of emanation as it disintegrates produces the same amount of chemical action. Conversely, W. Ramsay observed that a gram of radium gives 32 c.c. of the detonating gas in 100 hrs. A 5 per cent. excess of hydrogen is produced—he said that the excess is not explained by the oxygen having oxidized something, nor is it probable that the excess hydrogen is produced by the decomposition of radium itself. It is thought that the first stage of the reaction involves the formation of hydrogen peroxide: $2\text{H}_2\text{O}=\text{H}_2+\text{H}_2\text{O}_2$. According to F. L. Usher, a gram-atom of emanation decomposes about 154,000 mols of water. The subject has been studied by A. Debierne, W. Duane and O. Scheuer, C. Runge and G. Bodländer, K. Bergwitz, F. L. Usher, A. T. Cameron, M. Kernbaum, H. B. Baker, K. von Körösy, etc. Owing to the decomposition of water by radium preparations, the preservation of moist samples in sealed tubes may end in the bursting of the tube. A sealed tube with dry samples should have a piece of platinum wire sealed in the wall to dissipate the accumulating positive charge. B. Davis and C. W. Edwards, A. T. Cameron and W. Ramsay, O. Scheuer, and S. C. Lind found that with a mixture of **hydrogen and oxygen gases**, some water is formed—*q.v.*—and A. T. Cameron and W. Ramsay and W. Duane and O. Scheuer noted that water vapour is but slightly decomposed by the α -rays, $2\text{H}_2\text{O}=2\text{H}_2+\text{O}_2$. They also noted the decomposition of ice. H. J. H. Fenton showed that the speed of the decomposition of **hydrogen dioxide** is accelerated by radium radiations to twice the normal speed. M. Kernbaum showed that the amount of hydrogen peroxide formed in water is eq. to the deficiency of oxygen in the gaseous product. He said that the penetrating radiations result in the exclusive formation of hydrogen peroxide and hydrogen. M. S. Curie, A. Kailan, and M. Kernbaum made estimates of the energy utilized in these reactions.

S. C. Lind found that **hydrogen and bromine** unite to form hydrogen bromide when exposed to α -rays. The reverse reaction, the decomposition of **hydrogen bromide**, $2\text{HBr}=\text{Br}_2+\text{H}_2$, also occurs. A. T. Cameron and W. Ramsay noted the decomposition of **hydrogen chloride**, while M. Bodenstein, H. S. Taylor, and W. P. Jorissen and W. C. Ringer found that the reaction between **hydrogen and chlorine**—*q.v.*—is accelerated by radium radiations, but they noted no such effect with hydrogen and oxygen. Although a mixture of hydrogen and chlorine unites under the influence of radium radiations, hydrogen chloride, hydrogen bromide, and **hydrogen iodide** are decomposed. These reactions have been investigated by A. Kailan, M. S. Curie, W. Ramsay and A. T. Cameron, F. Giesel, J. Pinnow,

H. J. M. Creighton and A. S. Mackenzie, H. S. Taylor. F. Giesel observed that **barium chloride** which contains some radium chloride is spontaneously decomposed, and some chlorine is given off; similarly with the bromides—ozone and barium oxide are formed; some chlorate or bromate may also be produced. In aq. soln., F. Giesel noted that, owing to the action of the liberated bromine on barium hydroxide, some hypobromite is formed. F. L. Usher studied the decomposition of **ammonia** by radium emanation. The reaction was attributed to the β -particles. E. E. Wourtzel, and S. C. Lind also investigated the reaction. No definite evidence of the formation of ammonia from a mixture of hydrogen and nitrogen was observed. E. E. Wourtzel investigated the decomposition of **hydrogen sulphide**, and of **carbon dioxide**; the last-named reaction and the decomposition of **carbon monoxide** were also investigated by A. T. Cameron and W. Ramsay. E. E. Wourtzel found that **nitrous oxide** is decomposed, $N_2O = N_2 + O$, or $N_2O = N + NO$. G. H. Henderson found that **nitrogen iodide** is exploded when bombarded by radium radiations 3 or 4 cms. distant. The result is the same when all but the α -rays are screened.

P. Curie and A. Debierne, D. Berthelot, F. Giesel, L. Frischauer, etc., have indicated a number of chemical changes produced by radium radiations. Thus, monoclinic **sulphur** is changed into the rhombic form, and the velocity of crystallization of the sulphur is affected. Red amorphous **selenium** is crystallized, and the conductivity is affected in the same manner as it is by light, but to a smaller extent. In the presence of moist radium salts, the surface of **platinum** is blackened owing to the formation of a film of oxide. H. Becquerel found that yellow **phosphorus** becomes red; D. Berthelot, that **nitric acid** gives nitrous fumes, and **iodic acid** is decomposed; and G. Pellini and E. Vaccari made some observations on the last-named reaction. S. C. Lind observed a slight decomposition of **potassium iodide**, **lead iodide**, and **lead chloride** by the α -rays, while **lead bromide** was not decomposed. The valency of an element in its compounds is often reduced by radium radiations; thus H. Becquerel found **mercuric chloride** in the presence of oxalic acid forms mercurous chloride; and W. H. Ross, and A. Kailan noted the formation of ferrous from **ferric salts**. W. B. Hardy and G. Willcock found that soln. of **iodoform** in chloroform, carbon disulphide, or pyridine in darkness is coloured purple by radium radiations owing to the separation of iodine; the reaction was also studied by W. P. and W. E. Ringer. G. Pellini and E. Vaccari said that soln. of **propyl and isopropyl iodides** in iodoform are more strongly influenced by light than by radium radiations. G. Pellini and E. Vaccari did not observe any reaction between **uranyl nitrate** and oxalic acid, or between **sodium nitroprusside** and ferrous chloride under the influence of radium radiations while in darkness. According to V. Henri and A. Mayer, if a colloidal soln. of ferric hydroxide and silver be mixed with sodium acetate so that no colloid is precipitated, but, when exposed to the radium radiations, the positive colloidal **ferric hydroxide** is precipitated while the silver is not influenced. R. W. Lawson studied the disintegrating action of α - and β -rays on metals.

G. Schwarz found that under the influence of radium radiations, egg-shells are coloured brown; and F. Giesel, that paper is charred, and **celluloid** becomes brittle; J. B. Burke reported that **gelatine** is converted into turbid masses which appear to grow like living cells, but W. A. D. Rudge found that the effect is produced by the formation of insoluble sulphate from the sulphur dioxide contaminating the gelatine. G. Dreyer and O. Hanssen studied the coagulation of **albumen** by radium radiations; A. Fernau and W. Pauli, **proteins**—lecithin and cholesterol. W. B. Hardy noted that soln. of **globulin** change in colour and viscosity when exposed to Becquerel's or to α -rays. The action of these radiations on various **organic compounds** has been reported by J. J. Sudborough, Lord Blythwood, H. P. Martin and W. P. Morton, D. Berthelot, W. Ramsay and W. F. Cooke, P. Mesernitzky, O. Flaschner, H. Becquerel, A. Kailan, C. Doelter, W. P. Jorissen and W. E. Ringer, E. von Knaffl-Lenz and W. Wieckowsky, W. Caspari and

C. Neuberg, etc. **Vaseline** and **lubricants**, employed for stop-cocks and stoppers, may be changed into hard substances, and the cocks and stoppers are then moved with great difficulty; **caoutchouc** becomes hard and brittle; and **ebonite** is profoundly altered. A. Fernau studied the action of radium radiations on **sugar** and **agar-agar**. F. Sekera discussed the bearing of colloid chemistry on radioactivity.

According to F. Giesel,⁶ if the eyes be closed, and a tube of radium bromide be held near the forehead, the retina of the eye becomes phosphorescent, and light will be seen though the eyes are closed. A tube containing a little radium bromide when held near the skin for a few hours produces painful sores. Caterpillars and other small animals are said to be killed if shut up in a box with a minute fragment of radium. It is also claimed that the exposure of malignant skin diseases, superficial cancer nodules, etc., has proved beneficial in many cases, although the testimony of medical experts is not unanimous.⁷

§ 5. Analysis of the Radiations from Radium

The complexity of the radiations from radium is illustrated by the following facts: A few sheets of paper or a sheet of aluminium foil about 0.1 mm. thick will cut off a large part of the radiations, and a sheet of lead, about half a centimetre thick, will cut off nearly all the radiations. A residuum still remains unsuppressed even after passing through 15 cms. of lead or through a far thicker block of iron. Hence, **the radiations from radium are not homogeneous**. Again, the radiations from radium are not affected in the same way by a magnet. Some of the rays are not influenced, for they do not bend when placed in a magnetic field, these are called the γ -rays, these rays have the greatest penetrating power; others are bent *towards* the magnet, and are called the β -rays; while others are bent *away* from the magnet, and are called the α -rays; these rays have the least penetrating power. There are thus at least three distinct types of rays in the radiations emitted from radium salts:

1. Alpha rays.—The α -rays are slightly bent by intense magnetic forces.¹ The deviation is small and requires an intense magnetic field, so that at first the effect of the magnetic field on these rays was overlooked. E. Rutherford and co-workers, M. S. Curie, etc.,² have studied the behaviour of the α -rays in the electrostatic field. The results show that these rays carry a positive charge. **The general properties of the α -rays correspond with those of the canal rays in a vacuum tube.** The experimental evidence leads to the inference that the α -rays are streams of positively charged atoms projected from radium with a velocity approaching 20,000 miles per second. F. Giesel³ showed that the impact of α -rays on Sidot's blende produces a scintillating effect which J. Elster and H. Geitel, and W. Crookes observed through a lens, and found to be compounded of a number of distinct flashes of light. The emission of α -particles from radium salts can be illustrated very neatly by **W. Crookes' spintharoscope**. A small fragment of a radium salt supported at the tip of a wire (Fig. 3), in front of a screen, coated on the inside with zinc blende, is viewed in the dark through a magnifying eyepiece, which is focussed on to the screen by sliding it up or down the tube. Flashes of light are continually scintillating on the screen. R. K. Duncan likens the effect to the appearance of a swarm of fireflies on a dark night. The scintillations are caused by the rain of α -particles from the radium salt on to the screen. Each impact is marked by a flash of light. E. Regener showed that each α -particle produces one flash. F. H. Glew observed a similar effect with the diamond in place of Sidot's blende. E. Rutherford and

H. Geiger devised a method of counting the α -particles based on this effect—*vide infra* for an analogous electrical method. The effects of the magnetic and electric fields on the motion of the α -rays have enabled their velocity and charge to be calculated. The earlier observations were made on non-homogeneous rays, and are therefore rougher approximations than the results of the latter work.⁴ For the ratio e/m E. Rutherford obtained 6.1×10^3 , and for the velocity V , 2.5×10^9 cms. per sec.; A. S. Mackenzie obtained respectively e/m , 4.6×10^3 , and $V = 1.3 \times 10^9$ to 2.0×10^9 cms. per sec.; and T. Descoudres, e/m , 6.4×10^3 , and $V = 1.65 \times 10^9$ cms. per sec. The best representative value for e/m is 4.8×10^3 electromagnetic units. According to E. Rutherford and H. Geiger, the charge e on a single α -particle is 9.3×10^{-10} electrostatic units; and E. Regener obtained $e = 9.58 \times 10^{-10}$ electrostatic units or 3.18×10^{-20} electromagnetic units. A quantum of energy according to the quantum theory is between 4.65×10^{-10} and 4.77×10^{-10} electrostatic units. Hence, the α -particles from radium have two such charges; and m varies from 6.43×10^{-24} grms. to 6.59×10^{-24} grms. The mass of a hydrogen atom is 1.66×10^{-24} grms. Hence, the mass of the α -particle is four times that of the hydrogen atom. It is therefore inferred that the α -particles are atoms of helium, each carrying two positive charges. This conclusion was confirmed by direct experiment—*vide infra*, Fig. 4. The kinetic energy of an ejected α -particle is about 5.9×10^{-6} ergs. The total kinetic energy of the α -rays can be calculated from the number n of particles emitted by a gram of radium per hour, the mass, m , of the α -particle, and the velocity V since the total kinetic energy is then $\frac{1}{2}nmV^2$.

E. Rutherford and H. Geiger devised an electrical method for **counting the α -particles emitted by radium**. A small disc with a little emanation was fixed to a

FIG. 3.—Spinhariscope.

FIG. 4.—Apparatus for counting the α -particles emitted by radium emanation. (After E. Rutherford and H. Geiger.)

small iron cylinder and placed in a long glass cylinder—Fig. 4. The position of the radium disc could be adjusted by means of a magnet. This chamber—called the *firing chamber*—had a small mica window opening into a brass cylinder with ebonite ends and fitted with a central wire, *B*, connected with an electrometer. The brass cylinder was exhausted, and it then forms the *target or detecting chamber*. It was found possible to adjust the conditions so that two to five particles per minute passed through the mica window and upset the electrical equilibrium of the testing chamber. Each particle signalled its arrival by an unmistakable jump of the needle of the electrometer. The needle can be arranged so that its movements are recorded on

a chart (Fig. 5). Each jump represents the arrival of one particle in the "detecting chamber." Some of the jumps show that two particles sometimes arrive simultaneously or almost simultaneously. Given the size of the window and the distance of the source of the projectiles, simple arithmetic furnishes the number shot per minute in all directions from the radium emanation. The results were consistent

FIG. 5.—Chart showing movements of the needle of the electrometer on the arrival of α -particles.

with those obtained by counting the number of scintillations produced per minute when a zinc sulphide screen was used as a target, and show that about

3.4×10^{10} to 3.57×10^{10} of α -particles are shot per second from a gram of radium. Each α -particle passes into one atom of helium—*vide infra*.

The path of the ray through a moist gas has been made visible, owing to the condensation of water about the ions produced in the track of each α -particle. C. T. R. Wilson⁵ has photographed the fog so produced in the tracks of the α -particles, and the photographs make it very plain that the ionizing power of the particles rapidly reaches a maximum, and then rapidly sinks to zero as they pass into molecules of helium. In general, the tracks of the α -particles are straight lines, but in some cases there is an abrupt bend near the end of their ranges. It is supposed that this is due to the particle being deflected from its course as its speed is slackening because it encounters the nucleus of another molecule. It is assumed that the α -particle passes through all the atoms it meets, and in doing so loses kinetic energy because (i) the track is a straight line, and (ii) it cannot push the atoms it encounters out of its way because these atoms are heavier than itself, and it meets with hundreds of thousands. In ordinary molecular motions, two atoms are said to collide when their centres are so far from each other that the free path is extremely short—about 10^{-5} cms. The immense speed of the α -particle accounts for the difference in the two types of encounter. One atom cannot be penetrated by another when the mutual velocities are small, say, 10^5 cms. per sec.; but when these velocities are, say, ten thousand times greater, the atoms are not impenetrable. In the latter case, the kinetic energy is so great that intense forces are necessary to deflect the particles. When an α -particle happens to pass close to the nucleus of an atom with a large positive charge, the path will be deflected, and the rays scattered; the nearer the particle passes to the nucleus, the greater the deflection. On the assumption that the electric force about the nucleus varies according to the inverse square law, E. Rutherford showed that the α -particle will describe a hyperbolic orbit about the nucleus, Fig. 3 (3. 27, 3). The career of the α -particles has been investigated at different stages of its flight. At the beginning, when the speed and kinetic energy are greatest, the particle does *least* work in ionization. It is supposed that just as a swiftly speeding bullet can cut a clean hole in a pane of glass, while a slowly moving bullet will shatter the glass, so when the speed of the α -particles is greatest, they can pass right through the molecules of a gas without producing any appreciable effect; but towards the end of their flight the ionizing power is greater because of the greater shattering power of the slowly moving particles; and finally the particle ceases to ionize the gas and settles down to "ordinary life" as a helium molecule (or atom). The movement of the swiftly speeding α -particles is obstructed as they pass through a gas. The damping action of different media on speed of the α -rays is comparatively large, so that these rays have a low penetrative power. According to E. Rutherford and H. T. Brooks,⁶ they do not pass plates of mica or glass 0.1 mm. thick, nor plates of aluminium 0.05 mm. thick. Working with aluminium sheets 0.0034 mm. thick, and measuring the penetration of the α -rays by the ionization produced in air:

No. of plates of Al	0	1	2	3	4	5	6	7
Ionization	100	48	23	13.6	6.4	2.5	0.9	0

The maximum range of the α -particles is a characteristic of the parent substance. The velocity of the α -particle gradually decreases, but after the particle has travelled a certain distance the effects produced—ionization, scintillations, and photographic activity—cease abruptly. This distance is called the range of the α -particle in air. It is inversely proportional to the density of the air. The range of the α -particles in air ejected from radium is 3.00 cms., and the velocity 1.50×10^9 cms. per sec. If the introduction of a medium reduces the range to 2 cms., the stopping power of the medium is said to be eq. to 1 cm. of air. From the weight per unit area of the medium, say gold sheet, it is possible to calculate the number of atoms of gold through which the α -particles have passed, and the stopping power of the gold atom can be compared with that of the average air atom. H. R. von Traubenberg measured the range of the α -rays in solids. When expressed in 10^{-4} cms. units of length, the results are :

Li	Cu	Ag	Au	Ca	Mg	Zn	Cd	Al	Tl	Sn	Pb	Fe	Ni	Pt
129.1	18.3	19.2	14.0	78.2	57.8	22.8	24.2	40.6	23.3	29.4	24.1	18.7	18.4	12.8

and he represented the results by means of a formula involving at. wt., at. number, range, and sp. gr. K. Heil studied the effect of α -particles on crystals.

The stopping power, S , of a gaseous medium for the α -rays is determined, not by the physical or chemical properties of the gas, but solely by its molecular weight. In general, *the stopping power of an element is nearly proportional to the sq. root of at. wt.* This is the case whether a gas like hydrogen or a metal like gold is involved, and is shown by the results in Table III, due to W. H. Bragg. The at. wt. is the one quality of importance. The stopping power is not only independent of the physical

 TABLE III.—STOPPING POWER OF DIFFERENT ELEMENTS FOR THE α -RAYS.

Element.	S	$SA^{\frac{1}{2}}$	Element.	S	$SA^{\frac{1}{2}}$
Hydrogen . . .	0.24	0.240	Nickel . . .	2.44	0.319
Carbon . . .	0.85	0.246	Copper . . .	2.46	0.309

Sulphur . . .	1.76	0.312	Platinum . . .	4.14	0.297
Chlorine . . .	1.78	0.299	Gold . . .	4.22	0.301
Iron . . .	2.29	0.307	Lead . . .	4.27	0.298

state of an element, but it is also independent of the presence of neighbouring molecules. Chemical association is of no importance. J. L. Glasson formulates the stopping $= 0.262N^{\frac{1}{2}}$, where N is the at. number. W. H. Bragg and W. T. Cooke showed that the additive rule is applicable to chemical compounds, *the stopping power of a molecule is proportional to the sum of the at. wt. of the contained atoms.* Thus,

	O ₂	CO ₂	CO	C ₂ H ₂	C ₂ H ₄	C ₂ H ₆	CH ₄
Observed . . .	1553	2187	1437	1619	1906	2180	1242
Calculated . . .	1540	2200	1435	1618	1906	2194	1241

The stopping power is not altogether independent of the speed of the particle since the value of the constant is not the same for α -rays obtained in different rays, and of different speeds. W. Bothe discussed the scattering of the α -rays. P. Lenard and co-workers, A. Rüttenauer, and J. Königsberger have discussed the general equations for the velocity of particles in gases.

The kinetic energy of the α -particles passing through a gas is expended in doing work. The gas into which the α -particles are discharged becomes a conductor of electricity, and it acquires a greater chemical activity. The gas is said to be ionized. The relative degrees of ionization produced in a number of gases and vapours by the α -particles from radium have been studied by E. Rutherford,⁷ W. H. Bragg,

R. J. Strutt, T. H. Laby, R. D. Kleemann, etc. Representing the effect with air unity, the values with the hydrogen halides are 1.29, and with

N_2	O_2	H_2	CO	CO_2	NH_3	CH_4	C_2H_2	C_6H_6	C_6H_{12}
0.96	1.08	1.98	1.01	1.01	0.95	1.17	1.26	1.29	1.35

Excepting hydrogen, the ionization produced in gases by the α -rays is approximately proportional to the densities of the gases.

E. Rutherford, and W. H. Bragg showed that if r denotes the range of the α -particles yet to be completed, their velocity $V=k(r+a)^{\frac{1}{2}}$, where k and a are constants; and the former found that, as indicated above, the α -particle completes

FIG. 6.—Variation of Ionization in the Track of a Pencil of α -rays.

its range with much of its energy still unspent. H. Geiger represented the velocity by $V^3=kr$, where k is a constant; and if i denotes the ionization, r the range to be completed, $i^3=a/r$, where a is a constant. This curve—dotted line, Fig. 6—follows observations fairly closely. The rate at which energy is spent is proportional to VdV/dT , and therefore to $r^{-\frac{1}{2}}$ and to the ionization; so that ionization is proportional to the energy spent. Since the product iV is a constant, it follows that ionization is proportional to the time the α -particle spends within the atom; and also that ionization is a consequence of the presence of an α -particle within the atom, and depends for its amount on the time taken by the α -particle to cross the atom. The α -particles can travel but a few cms. before their initial velocity is exhausted, and they pass by de-electrification into ordinary molecules of helium. In air, for instance, H. Geiger, and W. H. Bragg found that the α -particles from uranium are slowest, and they can travel about 2.58 cms. at 0° and 760 mm. or 2.75 cms. at 20° and 760 mm., while those from radium gave a range of 3.13 cms. at 0° and 760 mm. or 3.36 at 20° and 760 mm. R. A. Millikan and co-workers showed that the velocity of the α -rays from radium is a different order from that employed by J. J. Thomson for positive-ray analysis (*q.v.*). G. H. Henderson found that the observed straggling of the α -particles is greater than that deduced from the present theory of the passage of α -particles through matter.

2. Beta rays.—The β -rays are readily bent by comparatively weak magnetic forces in the opposite direction to the α -rays; and they carry a negative charge.⁸ The general properties of the β -rays correspond with those of the cathode rays of the vacuum tube, for they appear to be negatively charged electrons or corpuscles projected from the radium salt with a velocity approaching 100,000 miles per second. The corpuscles in Crookes' tube travel a little faster than the β -rays from radium. A difference in speed might be expected from their different modes of generation.

FIG. 7.—Strutt's Radium Clock.

The following experiment—R. J. Strutt's radium clock—illustrates the character of the β -rays. A morsel of a radium salt is enclosed in a glass tube, A, Fig. 7, coated with a conducting material and ending at the bottom with a brass cap from which hang a pair of gold leaves. This system is fitted within a glass tube from which the air is exhausted. The inside of the tube is coated with strips of tinfoil, B, connected with the earth by the wire, C. The β -rays from the radium pass through the glass and leave the central system with a positive charge. This causes the gold leaves to diverge gradually until they touch the tinfoil, when they are discharged, and the leaves collapse. The process begins anew. This charge and discharge goes on continuously since the radium can emit these radiations an indefinitely long time. This arrangement is perhaps the nearest approach yet made to perpetual motion. The frequency of the cycle, of course, depends upon the amount of radium in the inner tube.

The β -rays are not homogeneous, but have widely different velocities; similar remarks apply to the value of the ratio e/m . On the assumption that the charge remains constant, this means that the mass m is not constant. W. Kaufmann showed that if m_0 be the mass of a particle at rest, and m the mass when its velocity is a fraction β of the velocity of light, $m=m_0(1-\beta^2)^{-\frac{1}{2}}$. For $\beta=\frac{1}{2}$, $m=1.15m_0$, and for $\beta=0.9$, $m=2.3m_0$. For low velocities, $m=m_0$, and $e/m=1.77 \times 10^7$ electromagnetic units, or 5.31×10^{17} electrostatic units; and $m_0=\frac{1}{1834}$ (oxygen=16). In absolute units, $m_0=0.876 \times 10^{-27}$ grms., and $e=4.65 \times 10^{-10}$ electrostatic units. R. A. Millikan gave $m_0=0.898 \times 10^{-27}$ grms., and $e=4.77 \times 10^{-10}$ electrostatic units. These give respectively 1.83×10^{-13} cms. and 2.00×10^{-13} cms. for the radius of the particles. F. Lerch discussed the effect of chemical treatment on the β -ray activity of radium.

The distribution of the β -rays of different velocity has been investigated by deflecting them in a magnetic field, and focussing the deflected rays on to a photographic plate. A homogeneous beam of β -rays produces a sharp band whose position enables the velocity to be calculated. Rays of lowest velocity are deflected most abruptly, and those of greatest velocity least abruptly. The result is the so-called *magnetic spectrum of the β -rays*. Usually, there are numerous sharp bands or lines on the photographic plate as well as a less intensely marked background which is continuous.

The passage of the β -particles through matter is not understood so clearly as in the case of the α -particles. It is not easy to get a homogeneous beam of β -rays. The velocity of the β -particles averages nearly ten times that of the α -particles, but the mass is so much less, that the momentum and kinetic energy of the β -particles are less than that of the α -particles. The kinetic energy of the α -rays is about 3.3 times that of the β -rays. Hence, the β -particles are more readily deflected in their encounters with atoms in their path. Instead of passing through matter in a straight line, the path is more or less tortuous. This is shown by C. T. R. Wilson's photographs⁹ of the track of the β -rays in air; the photographs were obtained by a process analogous to that used for the α -rays—*vide supra*. If the β -ray moves rapidly it produces a straight track, but the slower-moving rays have more or less tortuous tracks, being deflected hither and thither by collision with the molecules of the gas. C. Ramsauer, and H. F. Mayer studied the cross-sectional area of gas molecules towards slow electrons.

The absorption of the β -rays by matter sometimes follows the simple exponential law $I=I_0e^{-kd}$, where I_0 denotes the ionization current without an absorbing screen; I , the current for a screen of thickness d , and k is the coeff. of absorption. The value of k depends to some extent on the observation apparatus, and also on the source generating the β -rays; with some rays, the absorption curve is only approximately exponential; in other cases it is additive, $I=I_1e^{k_1d}+I_2e^{-k_2d}+\dots$. P. Lenard found the coeff. of absorption k for the cathode rays was approximately proportional to the sp. gr.; E. Rutherford found the law applied to the swifter β -rays from uranium; R. J. Strutt, for the complex β -rays of radium. E. Rutherford's results are shown in Table IV; the ratio k/D varies from 4.4 for carbon to 10.8 for lead. The plotting of the ratio k/D with the at. wt. shows that the variations in the values of this ratio are in harmony with the periodic rule. J. A. Crowther, H. W. Schmidt, etc., found that the ratio k/D follows the additive rule, so that if M be the mol. wt. of a compound, and A_1, A_2, \dots the at. wt. of the constituent atoms, $Mk/D=\Sigma(Ak/D)$. The range of the β -particles was measured by W. H. Bragg, G. A. Sutherland and L. H. Lamb, etc. The scattering of β -rays has been studied by H. Geiger and W. Bothe, J. A. Crowther and B. F. J. Schonland, etc. The β -ray spectrum has been investigated by L. Meitner, C. D. Ellis, and A. Smekal. The ionization of gases by β -rays has been studied by P. Lenard,¹⁰ W. Wilson, etc.

J. J. Thomson¹¹ found that matter traversed by α -rays furnishes a number of secondary radiations which he called *delta-rays*, or δ -rays. It has been proved that the delta-radiation is produced by slow-speed negative electrons which are large in number compared with the α -particles.

TABLE IV.—ABSORPTION OF β -RAYS BY ELEMENTS OF DIFFERENT DENSITY.

Element.	At. wt.	$\frac{k}{D}$	Element.	At. wt.	$\frac{k}{D}$	Element.	At. wt.	$\frac{k}{D}$
B	11	4.65	Cr	52	6.25	Ag	108	8.3

Ti	48	6.2						

From Isaac Newton's principle of action and reaction, it follows that when a particle of mass m and velocity v is ejected from an atom of mass M , the residual atom of mass $M-m$ must recoil with a velocity V such that $(M-m)V=mv$. The momentum of an α -particle is much greater than that of a β -particle, so that the velocity of recoil for the expulsion of an α -particle will be greater than for expulsion of a β -particle. The **recoil atoms** carry a positive charge, and they can be collected in a negatively charged plate. This enables a separation of some mixtures of radioactive substances to be made.¹²

3. Gamma rays.—The γ -rays are not affected by the most intense electric and magnetic forces.¹³ The γ -rays do not appear to be material particles at all; the experimental evidence shows that **the γ -rays are similar to, if not identical with,**

Röntgen rays. The chief difference is that the γ -rays are usually more penetrating than the X-rays, and they have a shorter wave-length. A diagrammatic illustration of the three types of radiation from radium is given in Fig. 8. A piece of radium is supposed to be placed in a lead vessel, A , sufficiently thick to prevent rays travelling through the walls. Under the influence of an intense magnetic field, the rays no longer travel in straight lines, but they are deflected, as shown diagrammatically in the figure. It will be observed that the α -rays and β -rays are alone corpuscular; the γ -rays are analogous with light rays of very small wave-length. Their penetrative power is very intense, and they can manifest their presence after passing through several inches

FIG. 8. — Diagrammatic Analysis of the Radium Radiations by a Magnet.

of metallic lead or several feet of metallic iron.¹⁴ K. W. F. Kohlrausch studied the secondary radiations produced when the γ -rays act on matter. The relative penetrative powers of the three types of rays for aluminium are roughly as $\alpha : \beta : \gamma = 10 : 10^3 : 10^5$. The passage of γ -rays and of X-rays through matter is a complex phenomenon which has not been elucidated. It involves the production of secondary X-rays ($q.v.$). C. T. R. Wilson found that the tracks produced by the Röntgen rays closely resemble those produced by the β -rays, and it is presumed that the Röntgen or γ -rays excite β -rays in matter on which they fall, and that the effects produced by the γ -rays are directly due to the β -rays to which they give birth. The ionization of media through which the γ -rays are passing, has been studied by H. Prelinger, V. F. Hess, W. H. Bragg, R. D. Kleeman,¹⁵ etc. L. de Broglie studied the conditions of equilibrium between atoms, electrons, and radiation in an enclosure at a constant temp.

The impact of cathode rays on matter gives rise to X-rays; and β -rays also behave similarly. It is therefore inferred that the γ -rays from radium are produced by the β -rays as they escape from the atom. The γ -rays produced by different radioactive substances differ greatly in amount and in penetrating power.

E. Rutherford explains this by assuming that the tracks of the β -particles from the nuclei of the different atoms outwards are differently related with the surrounding electronic rings. If the β -particle passes through a region in the atom where there are feeble forces, a weak pulse of the γ -radiation will be produced; whereas if the β -particle travels along a certain critical path within the atom and sets into vibration a ring of electrons, there is a considerable loss of energy which reappears as a γ -radiation of a wave-length characteristic of the disturbed rings of electrons. This explains the grouping of the magnetic spectrum of the β -rays. The continuous magnetic spectrum is supposed to be produced by the γ -rays ejecting β -particles of definite intensity from the atom. L. Meitner, and A. Smekal discussed the relation between the β - and γ -rays.

§ 6. The Properties of Radium

Radioactivity is the least manageable of natural processes. It will not be hurried or controlled. Nature keeps the management of this particular department in her own hands. Man views the phenomenon with hungry eyes, but his interference is barred out. He can only look on in wonder while it deploys its irresistible unknown forces.—ANON. (1907).

According to M. S. Curie and A. Debierne,¹ radium is a brilliant white metal; it blackens immediately on exposure to air, possibly owing to the formation of the nitride. A particle of the metal blackens white paper as if the latter had been charred. By extrapolation from the sp. gr. of calcium, strontium, and barium, the **specific gravity** of radium is nearly 6.0. The **melting point** is sharp at 700°. Radium is more volatile than barium; and it may be possible to separate the two elements by sublimation.

P. Curie and A. Laborde found that there is a continuous **emission of heat** from radium, so that the temp. of the element and its salts is always a little—about 1.5°—above the temp. of its surroundings. According to M. S. Curie, freshly prepared radium salts, solid or in soln., develop relatively little heat; but as time goes on, more and more heat is developed until, after about a month, the rate of development of heat assumes a stationary state. K. Angström observed that the rate of production of heat remained constant during seven months' observations. The month's period of induction, so to speak, has been traced to the development of certain more or less transient products of the disintegration of radium, which are themselves radioactive. In the stationary state, the rates of formation and dissipation are balanced. P. Curie and A. Laborde found that a gram of radium generates about 100 cal. of heat per hour; P. Curie and J. Dewar obtained a similar result; C. Runge and J. Precht gave 105 cal.; J. Precht, 113 cal., and later 134.4 cal.; F. Paschen, 126 cal.; E. Rutherford and H. T. Barnes, 110 cal.; K. Angström, 117 cal.; E. von Schweidler and V. F. Hess, 118 cal.; W. Duane, 120 cal., and later 104 to 117 cal.; and H. Petterson, 116.4 cal. J. Dewar found a slightly greater amount of heat to be developed in liquid hydrogen than in liquid oxygen or carbon dioxide.

P. Curie, and E. Rutherford, showed that the quantity of heat developed is but little affected by the external conditions. K. Angström found that neither an electric field nor a magnetic field makes any appreciable difference.

Normally, one gram of radium appears to evolve enough energy to raise a little more than its own weight of water from f.p. to b.p. every hour; this amount of heat is eq. to 118 cal. per hour, or about 1000 Cals. per annum. It has been estimated that a gram of radium will continue radioactive for about 2500 years, and it therefore follows that a gram of radium gives energy eq. to 5.5×10^8 cal., or to that obtained by burning $\frac{9}{10}$ ths of a ton of coal during the period of radioactive change. In other words, radium furnishes 250,000 times as much energy as is given by burning an equal weight of coal; or, as G. le Bon expressed it:

Matter, formerly regarded as inert and only able to give back energy originally supplied to it, is, on the other hand, a colossal reservoir of energy—infra-atomic energy—which it can expend without borrowing anything from without.

Much of the atomic energy of the radium atom is transformed into kinetic energy as the α -, β -, and γ -rays are ejected; the energy of the recoil appears as heat. The radium which has stood for some time contains other products, *vide infra*, and taking all these things into consideration, E. Rutherford and many co-workers find that the kinetic energy of the α -rays is 1.28×10^6 ergs per sec., or 110 cal. per hr.; that of the recoil action, 2.04 cal. per hr.; that of the β -rays is 3.8 per cent. of that of the α -rays or 4.18 cal. per hr., and that of the γ -rays is 5.2 per cent. of the α -rays or 5.72 cal. per hr., making a total of 122 cal. per hr. for a gram of radium in equilibrium with its disintegration products as far as radium C. The phosphorescence of radium was shown by W. Duane to have no perceptible influence on the development of heat—*vide* radium emanation.

Hence, **radium is continually doing work at an undiminishing speed without any external supply of energy**; otherwise expressed, the reaction is exothermal. Whence comes this supply of energy? How does the continuous evolution of heat by radium agree with the dogma that heat cannot come from nothing, but must come from some other source? The heat of a stove is derived from the oxidation of the fuel inside; with radium, it is assumed that the atoms (or molecules) are continually changing. If radium be an element, and the radium atoms are changing into something not radium, it follows that there must be some flaw in the hitherto universally accepted conception of an element.

W. H. Bragg and R. D. Kleeman,² H. Geiger and J. M. Nuttall, and E. Rutherford give for the **range of the α -particles** of radium in air at normal press. 3.13 cms. at 0° and 3.30 cms. at 15°; the **velocity** in air at 15° = 1.6×10^9 cms. per sec.; the **momentum**, 0.987×10^{-14} ; the **kinetic energy**, 0.794×10^{-5} ergs; and the **number of ions** produced by the absorption of an α -particle by air, 1.50×10^5 . The **radioactive constant**, γ —*vide infra*—is 0.000346 (year). E. Rutherford and H. Geiger estimated the **average life-period** of radium at 2500 yrs.; and the **half-life period** at 1760 yrs. (*vide infra*); B. B. Boltwood gave respectively 2880 and 2000 yrs., which are the best representative values, and B. Keetmann gave 1800 yrs. for the half-life period. The **parent** of radium is ionium (*q.v.*); the offspring, radium emanation (or niton) and helium. The nearest analogue is barium. When radium is freed from its emanation (*q.v.*) by heating it emits only α -rays and feeble β -rays, but no γ -rays. The α -ray activity of freshly prepared radium is but 20 per cent. of that which is exhibited by old preparations—*vide infra* radium emanation. O. von Bayer and co-workers found that there are two groups of **β -rays** with the respective velocities 0.52 and 0.65 in terms of the velocity of light. O. Hahn and L. Meitner, and L. Kolowrat observed that the **absorption coefficient of the β -rays** in terms of cms. of aluminium is 200.

The emission of the corpuscular radiations from radium and its compounds naturally suggests that the element is continually losing weight. A. Heydweiler³ reported that 5 grms. of a strongly radioactive preparation regularly lost 0.02 mgrm.

every 24 hrs.; but E. Dorn observed that 2.9 mgrms. of purified radium bromide did not lose 0.001 mgrm. in three months' time; and he showed that precautions must be taken against electrostatic effects in weighing preparations of radium. W. Wien, assuming that 6.6×10^9 β -particles are lost from a gram of radium bromide per second, estimates a loss of 1.2×10^{-10} grms. per annum; and if 10^{11} α -particles are lost per second, there will be a further loss of 6×10^{-6} grms. per annum.

F. Giesel⁴ found that radium salts impart a carmine-red colour to Bunsen's flame. If this flame be coloured by barium bromide, and a trace of radium bromide be introduced, the barium spectrum, particularly in the red, is masked. The **flame spectrum** of radium consists of lines and bands. There is a fine red band between wave-lengths 4700 and 6530, in which occurs a prominent line at 6653; there are orange-yellow lines at 6349, 6329, 6285, 6269, 6247, and 6210; a strong orange-yellow band between 6330 and 6130, and a feeble one between 6050 and 5900; a strong blue line at 4826; feeble blue lines at 4750, 4718, 4680 (possibly 4682), and 4595; and a feeble violet line at 4405. C. Runge and J. Precht observed these and other lines. It is not known whether the bands belong to the metal or to the bromide. E. Demarçay examined the **spark spectrum** of impure radium chloride first prepared by its discoverer, and he afterwards examined a specimen of a higher degree of purity. The spark spectrum has been examined by C. Runge and J. Precht, A. Miethe, F. Exner and E. Haschek, etc. The chief lines in the spark spectrum are 5813 in the yellow; 5660, 5616, 5601, 5556, 5502, 5406, 5400, 5319, 5097 in the green; 4856, 4826, 4682, and 4641 in the blue; and 4533, 4436, and 4340 in the violet; of these lines, only 4826 and 4682 appear in the flame spectrum. E. Demarçay found two bands in the spark spectrum of the chloride—one between 4621.9 and 4631.0, and the other between 4463.7 and 4453.4. These bands have not been observed by later observers, and it is therefore possible that they belong to the chloride. W. and M. L. Huggins studied the spectrum of phosphorescing radium. The **ultra-violet spectrum** has been examined by F. Exner and E. Haschek, G. Berndt, and W. Crookes; and the **arc-spectrum** by F. Exner and E. Haschek. The **Zeeman effect** has been observed by C. Runge and J. Precht. The spectral lines of the magnesium-calcium family can be grouped in three pairs; and the stronger lines of the radium spectrum are analogous with the stronger lines of the spectra of the other elements of the same family. The two lines of each of the three pairs are the same distance apart for any one element, but the distances apart of the lines in passing from one element to another increase in a regular manner with increasing at. wt. Thus:

	Magnesium.	Calcium.	Strontium.	Barium.	Radium.
At. wt. . . .	24.36	40.1	87.6	137.4	?
Distance . . .	91.7	223	801	1691	4858.6 units.

By plotting the at. wt. as functions of the distances between the lines, extrapolation furnished C. Runge and J. Precht, G. Rudolf, and W. M. Watts an approximate value for the at. wt. of radium. The extrapolation is easier if logarithms of the at. wt. and the distances apart of the lines be plotted. The graph for a group of chemically related elements then lies in a straight line, as indicated in Fig. 9. The series spectra of radium have been studied by W. Ritz, W. M. Hicks, E. Fues, and A. Fowler.

P. Curie and C. Chéneveau⁵ found the **magnetic susceptibility** of radium chloride to be $+1.05 \times 10^{-6}$, so that the element is feebly paramagnetic in combination. Barium is diamagnetic, -0.40×10^{-6} ; hence, observations on samples contaminated with barium are very unreliable. M. S. Curie found a mixture of barium chloride with 17 per cent. of radium chloride to have a magnetic susceptibility of -0.20×10^{-6} . S. Meyer, and P. Pascal have also made observations on this subject; and the latter found that the paramagnetism of radium occupies a position adjacent to the metals of the alkaline earths.

According to M. S. Curie and A. Debierne, radium decomposes water energetically and dissolves for the most part, showing that the oxide is soluble. M. S. Curie⁶

determined the **atomic weight** of radium. She found that 0.0919 grm. of the anhydrous chloride, whose spectrum showed the presence of barium but faintly, gave 0.0859 grm. of silver chloride. Hence, 0.0919 grm. of radium chloride contains 0.0213 grm. of chlorine; or 35.46 grms. of chlorine unite with 117.5 grms. of radium. Hence, the eq. of radium is 117.5. If radium chloride be RaCl_2 , by analogy with barium chloride, BaCl_2 , the at. wt. of radium is nearly 235. The bivalency of radium was confirmed by the diffusion experiments of G. von Hevesy on the assumption that the diffusion coeff. of the cation of radium chloride is represented by $1.25n^{-1}$ sq. cm. per day, where n denotes the valency; and H. Freundlich and G. von Elissafoff's observations on the electric endosmose phenomenon, where the vol. of liquid transported plotted with the conc. of the soln., gave curves in agreement with bivalent barium and magnesium salts, but not with sodium or aluminium. Later determinations by M. S. Curie, with purer materials and in larger quantities, gave 226.35; T. E. Thorpe, by a similar process, obtained 226.58; R. W. Gray and W. Ramsay, 226.36; and O. Hönigschmid, 225.97 ± 0.012 . The value obtained by C. Runge and J. Precht,⁷ from spectral observations, was 258, Fig. 9.

Fig. 9.—Relation between the Atomic Weights and the Distance apart of the Spectral Lines of the Calcium-Radium Family of Elements.

The salts of radium.—M. S. Curie⁸ said that radium is a higher homologue than barium in the alkaline earth family, and it stands in the same vertical column as the alkaline earths, and in the same horizontal period as the radioactive elements thorium and uranium. It is very similar in its analytical properties to barium; and R. de Forcrand places it in the electrochemical series between sodium and barium: Cs, Rb, K, Na, Ra, Ba, Sr, Li, Ca, . . . By extrapolation, he computed values for the heats of formation, solubilities, and heats of reaction of the halides, and the oxide. P. Lemay and L. Jaloustre found radium salts act as catalysts in some oxidation processes. Radium **chloride** and **bromide** are less soluble in water or in the corresponding haloid acids than the salts of barium. C. E. Scholl noted the formation of the complex salt $\text{RaBr}_2 \cdot 2\text{BaBr}_2 \cdot 6\text{H}_2\text{O}$ in acid soln. Radium **carbonate** and **sulphate** are also less soluble than the analogous barium salts, so that radium sulphate is considered to be less soluble than any other known sulphate. S. C. Lind and co-workers measured the solubility of radium sulphate and found that if a soln. mixed with barium sulphate be precipitated by adding a soluble sulphate, the ratio of barium to radium in precipitate and soln. is the same. The salts are not isotopic, and the phenomenon is therefore called *pseudoisotopy*. With radium sulphate alone, the mean value obtained for the solubility in water at 25° is 2.1×10^{-8} grms. per c.c., which is about one-hundredth of the solubility of barium sulphate. The presence of sulphuric acid up to 50 per cent. has no appreciable influence on the solubility. At higher acid conc., the solubility increases rapidly, the data obtained showing that the solubility is more than twelve times as great in 70 per cent. as in 60 per cent. acid. With $\frac{1}{10}N$ -sodium sulphate the solubility increases to 12.0×10^{-8} grms. per c.c. In dil. acid soln. the solubility increases about 50 per cent. when the temp. is raised from 25° to 35° , and the same increase is found when the temp. is raised to 45° . The observed value of the solubility of radium sulphate is in agreement with that expected from a comparison of the solubilities of the sulphates of calcium, strontium, and barium. There is very little difference in the solubilities of the nitrates of radium and barium. The chloride, bromide, nitrate, carbonate, and sulphate were prepared by M. S. Curie.

Radium bromide and chloride crystallize with two mols of water of crystallization which is lost at 100° , according to M. S. Curie—O. Hönigschmid said below 200° . According to the latter, radium chloride melts at a dull red heat without decomposition. L. Kolowrat found that radium chloride melts at about 1000° , and there

is a transition point between 830° and 920° . M. S. Curie found that molten radium chloride freezes to a glassy mass. The vitreous chloride glows with a bluish-violet light visible in daylight; in a darkened room, the phosphorescent light is so bright that the time can be read from a watch 20 cms. away. The vitreous salt glows more strongly than the salt dried at 200° . According to C. J. Joly, radium bromide melts at 728° , and if heated to 1600° , an insoluble glassy residue remains. According to F. Rinne, dihydrated radium and barium chlorides are isomorphous; both crystallize in the monoclinic system; the barium salt has the axial ratios $a:b:c=1.4494:1:1.1656$, and the radium salt $a:b:c=1.4485:1:1.1749$. M. S. Curie found that the crystals of radiferous barium chloride assume a yellow or rose tint some hours after they have been prepared; the intensity of the colour depends on the relative proportions of the two chlorides. The presence of barium appears to be necessary because highly purified crystals of radium chloride are not so discoloured. F. Kohlrausch and F. Henning measured the electrical conductivity, λ , of soln. of radium bromide, and on the assumption that the at. wt. of radium is 225, and the formula of the salt, $\text{RaBr}_2 \cdot 2\text{H}_2\text{O}$, obtained for soln. with N -gram-eq. per litre:

N . . .	0.05	0.02	0.01	0.005	0.002	0.001	0.0005	0.0002	0.0001
λ . . .	99.4	105.7	110.0	113.4	117.1	119.4	120.9	122.7	123.7

he also determined the temp. coeff. of the conductivity and found 0.0221 at 18° for soln. with 1.024 per cent. of $\text{RaBr}_2 \cdot 2\text{H}_2\text{O}$, and 0.0225 for 0.0286 per cent. soln. The ionic mobilities of the family of elements were Ca, 51.8; Sr, 51.7; Ba, 55.5; and Ra, 58. Electric endosmose phenomena of soln. of radium salts have been studied by H. Freundlich and G. von Elissaff; and the diffusion of radium salts in soln., by G. von Hevesy. E. Ebler and H. Herschfinkel prepared radium azide, $\text{Ra}(\text{N}_3)_2$, and found it behaves like the azides of the alkaline earths, decomposing into the metal and nitrogen between 180° and 250° . For the chemical properties of radium and its salts, *vide supra*, radium radiations.

According to W. Ramsay, a sample of radium bromide, $\text{RaBr}_2 \cdot 2\text{H}_2\text{O}$, lost water and some bromine when kept in a sealed tube for some time. O. Hönigschmid found when the anhydrous chloride had been kept for two years in a quartz tube, the containing vessel showed numerous fine cracks, and hence quartz is not suitable for keeping radium preparations. Glass tubes with a platinum wire sealed in the walls to dissipate the electric charge are best suited for preserving samples of radium salts. The electric charge which a vessel acquires may be considerable. E. Dorn and M. S. Curie noted such tubes may give sparks when cut with a file; and J. Precht, and P. L. Mercanton obtained explosions with radium preparations in tubes. According to G. Denigès, barium and radium salts can be distinguished microchemically since they give distinct and definite salts with iodic acid, providing the conc. of the salt soln. does not exceed 0.3 per cent.

§ 7. Radium Emanation—Niton

R. B. Owens¹ observed some irregularities in his measurements of the radioactivity of thorium compounds, which he traced to the action of currents of air, and E. Rutherford found that the effects were due to the emission of radioactive particles of some kind from the thorium compounds. This emanation is like a gas,

and it can be carried away by a stream of air: it can pass through a plug of cotton-wool, and be bubbled through soln. without losing its radioactivity. E. Dorn then showed that radium gives off a similar emanation. According to P. and M. S. Curie:

Any substance placed in the neighbourhood of radium acquires a radioactivity which persists for many hours and even days after the removal of the radium. This induced radioactivity increases with the time during which it is exposed to the action of radium up to a certain limit. After the radium is removed, it decreases rapidly and tends to disappear. The kind of substance exposed to the radium is almost a matter of indifference, for all substances acquire a radioactivity of their own.

This induced radioactivity has been traced to the continuous evolution of a substance from radium which behaves as if it were a radioactive gas, and which is adsorbed by substances in its presence. In his early work, to avoid the hypothesis implied by calling the radioactive substance a gas, E. Rutherford, its discoverer, called it an *emanation*. R. W. Gray and W. Ramsay called the emanation from radium, **niton**, Nt—*nitens*, shining—in reference to the solid; W. Ramsay and J. N. Collie the emanation from radium *exradio*; that from thorium, *exthorio*; and that from actinium, *exactinio*. Chemists appear to prefer the term niton; physicists, emanation.

The emanation from radium is of almost universal occurrence; it is found in air, spring-water, river-water, sea-water, volcanic products, minerals, and rocks. The occurrence of radioactive substances has been discussed in connection with radium, and most of these refer to this emanation. The emanation is obtained from radium preparations which have stood for some time. Fresh preparations are usually free from the emanation. The preparation of the emanation has been described by E. Rutherford, and by W. Ramsay and co-workers. The emanation is expelled by melting the radium preparation, or by dissolving the preparation in a suitable solvent. The emanation can then be obtained by shaking, or boiling the soln., or pumping off the gases. The emanation decomposes water, and it will then be contaminated with detonating gas. This is removed by sparking; the organic matter derived from the lubricants of stopcocks is burnt by passing the emanation over heated lead dichromate and the carbon dioxide absorbed by soda-lime; the oxygen and hydrogen are removed by passing the gas over heated copper and cupric oxide; the moisture is removed by phosphoric oxide; and the nitrogen, by heated lithium. The emanation can also be frozen by liquid air and the hydrogen and oxygen pumped from the solid. According to W. Ramsay, if the frozen solid is red, it can be assumed that the emanation is of a high degree of purity.

If N_0 be the number of atoms initially present, and N the number remaining after an interval of time t , E. Rutherford showed that the velocity of decay dN/dt is proportional to the number, N , of atoms present, or

$$\frac{dN}{dt} = -\lambda N \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where λ is a constant; hence, the law of decay is

$$N = N_0 e^{-\lambda t} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where the constant λ is invariable for a particular type of radioactive matter, but varies with different types of radioactive matter, and it has therefore been called the *radioactive constant*. Consequently, the law of radioactive change formally resembles the law of mass action. It is convenient to express the decay in terms of the so-called *half-life period*, that is, the interval required for the activity or the number of atoms present to fall to half value. Hence, $N = \frac{1}{2}N_0$, and $\frac{1}{2} = e^{-\lambda t}$, or $2 = e^{\lambda t}$, or $\log_e 2 = \lambda t$, or $\lambda t = 0.69315 \dots$; consequently the half-life period, t , or the radioactive constant, λ , can be calculated when the other value is known. Again, the expression $N = N_0 e^{-\lambda t}$ means that any atom may exist unchanged for any time from zero to infinity; but after a time t , the number, dN , which changes in the time dt is equal to $\lambda N dt$, or to $\lambda N_0 e^{-\lambda t} dt$; but each of these atoms has a life t , so that the *average life* of the whole number is, by the laws of probability, $\int \lambda t e^{-\lambda t} dt$ between zero and infinity, i.e. λ^{-1} ; or, the average life of an atom is the reciprocal of the radioactive constant. A. T. Cameron illustrates the meaning of the term average life employed in the study of radioactivity as follows: "If a church at a fixed time contains a number of people of different ages, then, given the number of years each person will live after leaving

the church, the average life of the congregation is reckoned from the time fixed by that church attendance." This is not the average life taken from the time of birth used in computing insurance rates.

The decay of the radium emanation is comparatively slow, measurements of the average life, and the half-life period have been made. P. Curie found 3.99 days for the half-life period, E. Rutherford and F. Soddy gave 3.71 days; A. Bumstead and L. P. Wheeler, 3.88 days; H. Mache and S. Meyer, 3.89 days; O. Sackur, 3.86 days; G. Rümelin, 3.75 days; M. S. Curie, 3.85 days; and E. Rutherford, 3.846 days. The best representative values of the decay constants in day, minute, and second units are :

	Days.	Hours.	Minutes.	Seconds.
Half-life period . . .	3.85	0.924×10^2	5.55×10^3	3.33×10^5
Average life . . .	5.55	1.330×10^2	8.00×10^3	4.80×10^5
Radioactive constant . .	0.180	7.50×10^{-3}	1.25×10^{-4}	2.085×10^{-6}

The products of the decomposition of the emanation of radium are (i) α -particles which, when the charges are neutralized, furnish helium gas; and (ii) a radioactive solid named radium A, which adheres to the surfaces of bodies. Radium A itself quickly undergoes a series of changes, so that the apparent product of the decomposition of radium emanation is a radioactive deposit which is a complex mixture included in the general term *active deposit*. The radioactivity produced on inactive bodies by a film of the active deposit is the cause of the *induced or excited radioactivity* discovered by P. and M. S. Curie in connection with radium, and by E. Rutherford in connection with thorium.

A genetic relationship between helium and the radioactive minerals was suspected by E. Rutherford and F. Soddy because helium is occluded in these minerals. W. Ramsay and F. Soddy found that when radium emanation is kept in a sealed glass tube, it shows the spectrum of helium, which gradually grows brighter as the emanation decays. One volume of the emanation furnishes roughly three vols. of helium. Further evidence in this connection was obtained by P. Curie and J. Dewar, T. Indrikson, F. Himstedt and S. Meyer, etc. Radium emanation thus decomposes into radium A and α -rays. E. Rutherford and T. Royds gave direct evidence that the accumulated α -particles consist of helium. They enclosed some radium emanation in a thin-walled glass tube surrounded by a vacuum jacket, Fig. 10. Each vessel was gastight; α -rays from the radium emanation could penetrate the walls of the inner vessel, but not the walls of the outer tube. By raising the left mercury reservoir, the gas in the annular space could be compressed in the spectrum tube, and there sparked, and examined spectroscopically. In two to six days' time, a gas with the spectrum of helium accumulated in the annular space between the two tubes. To show that the helium was not derived by diffusion from the inner tube, the emanation was removed and helium substituted. No trace of helium could be detected in the outer vessel after standing several days. This and other experiments have proved that the **radium passes into helium via the emanation**. Otherwise expressed, helium is one decomposition product of radium. Still further, the α -rays are streams of positively charged particles, and each particle carries two unit positive charges. **Radium emanation decomposes, continuously and spontaneously, into a radioactive solid and α -particles; each α -particle is an atom of helium carrying two unit positive charges.**

Helium, said E. Rutherford, is not to be regarded as a decomposition product

FIG. 10. — Rutherford's Experiment showing the change of α -particles into Helium.

of radium in the ordinary sense of the word ; rather is it a by-product derived from the emitted α -particles. **The production of helium is independent of the matter from which the α -particles have been derived.** A. Debierne observed the change with α -rays from actinium ; F. Soddy, from thorium and uranium minerals ; M. S. Curie and A. Debierne, and B. B. Boltwood and E. Rutherford, from polonium ; R. J. Strutt, from thorianite and pitchblende ; B. B. Boltwood, from ionium ; and E. Rutherford and B. B. Boltwood, from radiolead.

J. Dewar found a gram of radium, in equilibrium with the active deposit and emanation, furnished 169 c.mm. of helium at 0° and 760 mm. per annum. B. B. Boltwood and E. Rutherford obtained 156 c.mm. Assuming that each α -particle produces one helium atom, and that 3.57×10^{10} α -particles are emitted by a gram of radium, then, under the above conditions, where four emitters of α -particles are in equilibrium with radium, 14.28×10^{11} α -particles are emitted per second, and this is eq. to 162–167 c.mm. of helium per annum.

The rate of decay of radium emanation is quite independent of any known condition.—E. Rutherford found that it is independent of *concentration or pressure*, showing that it is not affected by the bombardment of its own radiations ; P. Curie found the rate to be independent of the *nature and pressure of surrounding gas* ; and he detected no difference whether the *temperature* be -180° or 450° ; E. Rutherford observed no difference in the rate at ordinary temp. and at the temp. of liquid air ; W. Makower and S. Russ obtained the same results at ordinary temp. and at 1100° ; E. P. Adams, F. Wallstabe, and R. B. Moore detected no difference when the emanation is *dissolved in water*, and F. Wallstabe, when *dissolved in toluene*. The fact that the rate of decay of the emanation is independent of physical and chemical conditions led P. Curie to suggest that the decay of the emanation could be employed to fix a standard of time.

E. Rutherford and F. Soddy showed that the emanation is singularly inert ; it is not affected by the mineral acids or by other liquid reagents, nor is it affected when heated to a high temp. with platinum, lead chromate, magnesium, etc. W. Ramsay and F. Soddy found that the emanation suffers no change when heated for an hour in the presence of a mixture of lime and magnesium ; it is not influenced by burning phosphorus ; nor by sparking a mixture of the emanation with oxygen over alkali-lye. J. J. Thomson, and F. Himstedt found that conc. acids, alkali-lye, red-hot copper or magnesium, the electric spark, and the silent electric discharge are without influence. Hence, said E. Rutherford, and W. Ramsay, radium emanation is chemically inert, and it behaves like a gas of the argon family.

The determination of the **atomic weight** of niton is difficult, because the available quantities are small, and because it is adsorbed by the containing vessel. If radium, at. wt. 226, is transformed into niton by the loss of an atom of helium, at. wt. 4, the at. wt. of niton should be near 222. R. W. Gray and W. Ramsay measured the **relative density** of about 0.001 mgrm. of niton, by means of a micro-balance, sensitive to one-millionth of a mgrm. Assuming that niton is a monatomic gas, they obtained 227, 226, 225, 220, and 218—average, 223. These results are in accord with theory ; and show that niton is the heaviest gas known, being 111 times the density of hydrogen. The normal density was found to be 0.00996 when that of oxygen is 0.001429. The at. wt. so determined is in agreement with diffusion and effusion methods of determining gas densities. E. Rutherford found 0.06 c.mm. of gaseous niton did not occupy in the liquid state more than 1.2×10^{-4} c.mm. Hence the **specific gravity** of the liquid is to that of the gas $= 6 \times 10^{-2} / 1.2 \times 10^{-4} = 500$. R. W. Gray and W. Ramsay obtained 555. Hence the sp. gr. of the liquid, according to the former, is about 5, and, according to the latter, about 5.5.

E. Rutherford,² and W. Ramsay and co-workers found that niton follows Boyle's gas law. The constancy of the product *pv*, particularly for large volumes, is characteristic of permanent gases. When partially purified niton is forced into a capillary, there are marked changes in vol. during the first few hours, due to the chemical actions of the α -radiation from niton on the gaseous impurity ; the vol.

may expand or contract depending on the nature of the impurity; with purified niton the changes are less marked. After the initial changes, the vol. does not alter very much with time. The **compressibility** of niton between $p=0$ and $p=1$, is -0.019157 . R. W. Gray and W. Ramsay found the **vapour pressure**, p , to be

	-74.5°	-66.1°	-53.1°	-48.5°	-43.1°	-31.0°	-12.8°	$+1.5^{\circ}$
p	100	200	500	760	1000	2000	5000	10,000 mm.

E. Rutherford gives 9 mm. at -127° ; 50 mm. at -107° ; 250 mm. at -78° ; and 760 mm. at -65° . Niton behaves like ordinary gases, exhibiting a definite vap. press. for a definite temp. G. Rudolf found the values of f in J. H. van der Waals' formula, $\log p_c - \log p = f(T_c T^{-1} - 1)$, varied from 2.29 at 202.6° K. to 1.873 at 372° K.

A. O. Rankine found the coeff. of **viscosity** of the gas to be 0.0002130. E. Rutherford and H. T. Brooks, P. Curie and J. Danne, and L. Chaumont determined the coeff. of **diffusion** of niton gas in air, and found 0.1 sq. cm. per sec.; according to G. von Hevesy, this number is too high, and he considers the value is less than 0.07 sq. cm. per sec. at room temp. The diffusion constant obtained directly is too high for the at. wt. and T. Graham's rule. F. Wallstabe measured the diffusion of niton in water and in toluene, and found respectively 0.066 and 0.168 sq. cm. per day. E. Rona's value is 0.985 at 18° for water, and E. Ramstedt's value is 0.820. The last named also calculated the molecular diameter to be 1.85×10^{-8} cms. A. Debierne determined this **effusion** of the gas through a fine aperture; W. Makower compared the effusion with that of hydrogen, oxygen, carbon dioxide, and sulphur dioxide; and P. B. Perkins, with mercury vapour at 250° . The results are in rough accord with the observed at. wt.

The **specific heat** of niton has not been determined; for a monatomic gas of at. wt. 222-223, the at. ht. should be about 3; the sp. ht., $c_v = 0.0135$; $c_p = 0.0225$; and $c_p/c_v = 1.667$. Many of the effects ascribed to radium or radium-rays are really due to the occluded emanation, or to the active deposit produced by the decay of the emanation. Thus, E. Rutherford and H. Robinson analyzed the **emission of heat** in cal. per gram of radium:

	α -rays.	β -rays.	γ -rays.
Radium . . .	25.1	—	—
Emanation . . .	28.6	—	—
Active deposit . . .	69.9	4.7	6.4
Total . . .	123.6	4.7	6.4 = 134.7

E. Rutherford and F. Soddy studied the temp. of condensation of niton to the liquid state in gaseous mixtures under low partial press. A. Laborde determined the temp. of condensation in spirals of copper, lead, silver, and glass; he obtained the same temp. for the metals -160° to -161.7° ; but for glass, he obtained -164.4° . R. W. Boyle did not get so marked a difference for glass. P. Curie and J. Danne, J. J. Thomson, F. Himstedt, and H. Ebert condensed niton to a liquid by cooling in liquid air. R. W. Gray and W. Ramsay found the **boiling point** of niton to be -48.5° , but later gave -62° ; E. Rutherford found -65° . R. W. Gray and W. Ramsay found the **melting point** to be -71° , at which temp. the vap. press. is still about 500 mm.—the solid is opaque and crystalline. Liquid niton undergoes a marked variation in colour as the temp. is lowered; at ordinary temp. the liquid is colourless and transparent. When cooled below the f.p., -71° , the condensed niton exhibits a brilliant phosphorescence, which becomes yellow as the temp. is lowered, and it appears orange-red at the temp. of liquid air; on raising the temp., the red phosphorescence becomes yellow at about -118° . These colours are complicated by the phosphorescence of the glass—in a quartz tube, the colour appears blue; in a soda-glass tube, lilac; and in a lead-potash-glass tube, bluish-green. R. W. Gray and W. Ramsay gave 104.5° for the **critical temperature**, and 47,450 mm. or 62.4 atm. for the **critical pressure**. G. Rudolf calculated the mol. latent heat of vaporization from W. Nernst's equation, $M\lambda = T(9.5 \log T - 0.009T)$,

and obtained for $T=211^{\circ}$ K., 4387 Cals.; and from E. Clapeyron's equation, $M\lambda=3960$ Cals. Assuming that $M\lambda=3950$ and $M=222.5$, the latent heat of vaporization is 17.75 Cals. per gram. G. N. Lewis and co-workers gave 41.81 for the **entropy** of niton at 25° and atm. press.

Radium emanation, or niton, emits only α -rays. W. H. Bragg and R. D. Kleeman,³ H. Geiger and J. M. Nuttall, and E. Rutherford give for the **range of the α -particles** of niton in air at normal press., 3.94 cms. at 0° , and 4.16 cms. at 15° ; **velocity** in air at 15° , 1.73×10^9 cms. per sec.; the **momentum**, 1.06×10^{-14} ; the **kinetic energy**, 0.915×10^{-5} ergs; and the **number of ions** produced by the absorption of an α -particle by air, 1.74×10^5 . As previously indicated, the **radioactive constant**, λ , is 0.1800 day, or 0.0075 hr., or 2.083×10^{-6} sec.; W. Bothe and G. Lechner gave $\lambda=0.1819$ day, or 2.106×10^{-6} sec.; the **half-life period** is 3.85 days; W. Bothe and G. Lechner gave 3.810 days; the **average-life period** is 5.55 days. The **parent** is radium, the offspring, radium A and helium, and the nearest analogue xenon. G. H. Briggs, and E. M. Wellish concluded that only a fractional part of the recoil atoms of radium emanation are positively charged at the end of their path; G. H. Henderson concluded that all are charged.

E. Rutherford observed a kind of relationship between the period of the transformation of a product and the velocity of the α -rays which it expelled. The greater the velocity of the α -rays, the shorter the period of the transformation. A relation is rendered evident by plotting the logarithms of the radioactive constants and the ranges, Fig. 11, of some decay products of uranium. H. Geiger and

FIG. 11.—Relation between the Range and Life Period of the Decay Products of Uranium.

J. M. Nuttall represented the relation by $\log \lambda = a + b \log R$, where λ denotes the transformation constant; and R the range of the α -particles, while a and b are constants; H. A. Wilson gave $\log \lambda - \log R = a + bR^{-\frac{1}{2}}$; R. Swinne gave $\log \lambda = a + bV^n$, where V denotes the velocity of the α -particle; a and b are constants; and $n=1$ or 2; and H. T. Wolff gave other expressions. E. Rutherford interprets these observations to mean that "the chance of an atom breaking up is greater, the greater the surplus energy to be got rid of to form the next product of the series." H. Geiger showed that in order that a radioactive substance may emit a

particle of short range, say 1 cm., the period of transformation would be so long that the activity of the product would be too small to detect; and it corresponds with the fact that no known product emits α -particles of such short range. F. Kirchhoff has discussed this question.

The **phosphorescent** effects produced by radium emanation have been discussed in connection with the properties of radium radiations. A. W. Porter and C. Cuthbertson⁴ found the **index of refraction** of an impure sample of niton to be 1.000840; a sample further purified gave 1.000916; and it is inferred that the value would be 1.00092 with highly purified niton. The spark **spectrum** of niton is characteristic, and quite distinct from that of radium and of helium. The discharge in a tube of niton is bluish, and not so intense as that of a helium tube. The spark spectrum shows a group of strong green lines and another group of violet lines. W. Ramsay and J. N. Collie, and R. E. Nyswander and co-workers made some observations on this subject. E. Rutherford and T. Royds photographed the spectrum, and compared it with that of helium. Their results are shown in Fig. 12; the numbers represent wave-lengths. W. Ramsay and A. T. Cameron also published results derived from these photographs, but T. Royds showed that with the exception

of the more intense lines of niton, the spectrum coincided with that of xenon, and there thus appeared to have been an accidental and unsuspected contamination with xenon—W. Ramsay said *die einzige mögliche Erklärung ist dass unter gewissen Umständen Niton in Xenon zerfällt!* H. E. Watson confirmed the results of E. Rutherford and T. Royds, and the last named found some additional lines in the ultra-violet. There is no clear evidence of the spectrum lines of niton in stellar spectra. The saturation current produced between two extended plate electrodes by radium emanation has been studied by L. Flamm and H. Mache.

FIG. 12.—Spark Spectral Lines of Helium and Niton.

M. S. Curie ⁵ showed that water becomes radioactive by exposure to the emanations of radium, and this was ascribed to the absorption of the emanation by water. The discovery that well-water and spring-water contain much niton, but no radium, showed that the emanation must be soluble in water. Qualitative observations were made by P. Curie and A. Debierne, and F. Himstedt, R. Schenck and A. Schulze; while H. R. von Traubenberg, and H. Mache showed that **the solubility in water** resembles that of other gases. If a vol. v_1 of air or other gas, and a vol. v_2 of liquid be confined in a vessel; and when the system is in equilibrium, a vol. e_1 of niton be present in the gas, and a vol. e_2 be dissolved in the liquid; then, the conc. of niton in the gas is e_1/v_1 , and in the liquid, e_2/v_2 . The ratio of these conc. is a measure of the **absorption coefficient**, α , such that $\alpha = e_2 v_1 / e_1 v_2$. H. R. von Traubenberg obtained $\alpha = 0.33$; and H. Mache, 0.32. R. Hofmann showed that the value of α decreased with temp.; and M. Kofler, that α decreased with increasing conc. of niton dissolved in the water. S. Meyer compared the observed values of α with those calculated from the relation $\alpha = 0.105 + 0.405e^{-0.0502\theta}$, and the results are:

	0°	5°	10°	20°	40°	60°	80°	100°
α (Obs.) .	0.510	0.420	0.350	0.255	0.160	0.127	0.112	0.107
α (Calc.) .	0.510	0.420	0.351	0.254	0.159	0.125	0.112	0.108

The agreement is excellent. The solubility formula $\alpha = a + be^{-c\theta}$ applies also to the gases argon, nitrogen, hydrogen, oxygen, carbon monoxide, and nitrogen monoxide, where the constant c has the same value. It is remarkable that at 100°, ten per cent. of niton remains dissolved in the water. R. W. Boyle found that the solubility decreases rapidly with temp., but for a definite temp., the coeff. is independent of the conc. of the gas, and also independent of the nature and press. of the inactive gas mixed with the niton. G. Jäger represented the solubility by the formula, $\alpha = e^{-W/RT}$, where W denotes the work which the surface forces perform in removing a mol at the absolute temp. T from the liquid into vapour, R is the gas constant. R. W. Boyle found for the heat of soln. Q cals., of niton in water:

	0°-5°	5°-10°	10°-15°	15°-20°	20°-25°	25°-30°	303-5°
Q .	6.7	6.3	5.8	5.6	5.5	5.1	4.7

H. Mache and S. Meyer, H. Sjögren and N. Sahlborn found values of a for a number of spring-waters; M. Kofler measured the absorption coeff., a , of niton in a number of salt soln., and found at 18° for soln. with the bracketed sp. gr., *mercuric chloride* (1·049), $a=0\cdot250$; *silver nitrate* (1·190), $a=0\cdot192$; *potassium permanganate* (1·038), $a=0\cdot194$; *ferrous sulphate* (1·226), $a=0\cdot081$; *ammonium chloride* (1·078), $a=0\cdot096$; *lead nitrate* (1·237), $a=0\cdot166$, and (1·283), $a=0\cdot143$; *potassium chlorate* (1·175), $a=0\cdot061$, and (1·028), $a=0\cdot187$; *potassium ferrocyanide* (1·107), $a=0\cdot102$; *zinc sulphate* (1·346), $a=0\cdot041$, and (1·199), $a=0\cdot092$; *cupric sulphate* (1·193), $a=0\cdot075$, and (1·042), $a=0\cdot194$; *sodium chloride* (1·203), $a=0\cdot042$, (1·008), $a=0\cdot239$; *sea-water* (1·028), $a=0\cdot165$; *sugar soln.* (1·214), $a=0\cdot114$, and (1·082), $a=0\cdot188$; and aq. soln. of *alcohol* (0·977), $a=0\cdot300$, and (0·800), $a=5\cdot606$. Eq. soln. of different salts have nearly the same coeff.; *sodium chloride* (1·0392), *potassium chloride* (1·0449), and *cupric sulphate* (1·0776) have the respective values $a=0\cdot165$, $0\cdot163$, and $0\cdot157$. R. W. Boyle also made observations with sea-water, and he found that the gas is virtually insoluble in *mercury*. R. Hofmann, A. Lurié, and E. Ramstedt referred the solubilities in some liquids to the formula $a=a+bc^{-\theta}$, when the temp. θ is expressed in hundredths of the interval between the m.p. and the b.p.; $a+b$ denotes the solubility at the m.p. Thus,

	m.p.	b.p.	a	b	c
Carbon disulphide	-110°	46·3°	13	900	0·054
Ethyl ether	-117·6°	34·6°	10	700	0·055
Toluene	-92·4°	110·7°	2	125	0·045
Chloroform	-63·2°	61·2°	9·5	90	0·043
Ethyl alcohol	-117·6°	78·4°	2·5	86	0·046
Acetone	-94·6°	56·1°	4	68	0·046
Ethyl acetate	-83·8°	77°	4	66	0·048
Xylene	-55°	139°	1	68	0·045

At temp. between 18° and 20°, a for *olive oil* and similar oils is 28; for *carbon disulphide*, 23; *cyclohexane*, 18; *hexane*, 17; *turpentine*, *ethyl ether*, *chloroform*, and *amyl acetate*, 15; *toluene*, *benzene*, and *xylene*, 13; *vaseline*, and *petroleum*, 10; *paraffin*, 9; *ethyl acetate*, 7·4; *acetone*, 6·3; *ethyl alcohol*, 6·2; *aniline*, 3·8; *glycerol*, 1·7; E. Ramstedt gives 0·21 for *glycerol*, and A. Lurié a higher value. G. Hofbauer found that with the homologous *alcohols* and *fatty acids*, the solubility increases as the CH_2 -groups increase. H. Mache and E. Suess found for *blood*, $a=0\cdot42$; and E. Ramsauer and H. Holthusen, 0·31 at the body temp., 37°. A. Schulze also measured the solubility of niton in a number of organic liquids—*toluene*, *ethyl ether*, *ethyl acetate*, *ethyl alcohol*, *chloroform*, *acetone*, *carbon disulphide*, *hexane*, *aniline*, and *benzene*—at different temp.

The radioactivity which a substance acquires when exposed for some hours to niton is due to the deposition of a radioactive deposit which decays rapidly with time and becomes very small in about 12 hrs.; but P. Curie and J. Danne⁶ showed that the acquired radioactivity of many solids—*caoutchouc*, *celluloid*, *wax*, *paraffin*, *mcerschaum*, *platinum black*, *glass*, *alum*, *clays*, etc.—persists for many days. This was traced to the absorption or occlusion of the gas. The decrease is due partly to the decay of the emanation *in situ*, and partly to the escape of the occluded gas into the surrounding air. A similar effect was observed with some metals—*lead*, *platinum*, *aluminium*, *copper*, *bismuth*, and *silver*. L. Bunzl, E. Rutherford, A. S. Eve, J. Satterly, R. W. Boyle, and H. Mache and T. Rimmer have investigated the remarkably strong absorbent powers of *charcoal*, notably *cocoa-nut charcoal*, for radium emanation. G. von Hevesy found animal charcoal not as good. W. Mohr thus represented the percentages absorbed at different temp.:

-182°	-120°	-78°	-10°	0°	22°	100°	165°	250°	395°	490°
100	91·5	81·1	64·98	59·23	57·18	43·85	34·18	20·31	15·70	7·14

C. Porlezza and G. Norzi found that at -77° wood charcoal removes all the emanation from the gaseous exhalations of fumeroles; at -20°, about half is removed; and at 10° and higher temp., very little change occurs. E. Henriot observed that wood charcoal below 18° completely removes all the niton from an enclosed gas, while above 300°, virtually none is absorbed; between these temp., the quantity is a function of the temp. H. Herschinkel found that admixtures of iron or uranium hydroxide, didymium fluoride, or iron chromate facilitate the expulsion of niton from radium. P. L. Mercanton found that niton does not diffuse through glass even when the latter is heated to its softening temp. The absorption is to a large extent dependent on the grain size of the material; the temp.; the amount of

moisture present; etc. E. Ebler and M. Fellner found colloidal substances—silicic acid, arsenic sulphide, and organic colloids—hold the emanation very tenaciously. The action has been studied by K. Horovitz and F. Paneth. Many metal salts occlude radium emanation; the oxides, hydroxides, chlorides, and bromides are more active than the carbonates or sulphates. M. S. Curie and A. Debierne, E. Rutherford, B. B. Boltwood, S. Meyer and V. F. Hess, and H. Holthausen have studied the occlusion of niton by solids.

Ordinary radium compounds in the solid form allow very little emanation to escape at ordinary temp., so that the greater part remains occluded with the parent. There is no evidence that the emanation is chemically combined with the radium; neither radium nor radiferous barium absorb any marked proportion of the emanation which has been released. The liberation of niton is facilitated by a rise of temp., the process is one of diffusion, and is facilitated by decreasing the grain-size of the material. As previously indicated, the occluded niton is liberated by fusing the material, or by dissolving it. M. S. Curie showed that both methods yield the same amount of niton for a given weight of radium. Dihydrated radium chloride loses its niton below the m.p., but when the water of crystallization has been expelled, a higher temp. is needed to drive off the niton. L. Kolowrat found that the amount of niton liberated from radium preparations depends not only on the temp. but on the time of heating. With anhydrous radium chloride, the effect of temp. is very slight up to 300°–400° and but little niton is lost; there is then a very rapid increase in the rate at which niton escapes up to 830°; above this the rate of escape decreases to a minimum at about 920°; and the rate then increases up to the temp. of fusion, about 1000°, when the whole emanation is given off. The fall in the rate of evolution of niton between 830° and 920° is connected with a change in the physical state of the salt. The loss of niton at a given point on the time-temp. curve is independent of the total amount accumulated in the body. The fact that the emanation can be driven off from radium with a greater velocity as the temp. is raised has no reference to the statement that radioactive processes are independent of the physical conditions, because the emanation is already there. The rate at which the radium manufactures the emanation is not affected by temp., etc.

Starting with a radium preparation freed from the emanation, and confined in a sealed vessel to prevent the loss of the small fraction which might otherwise escape by diffusion, if q atoms of niton are produced per second, and N atoms of niton be present at the time t , λN particles of niton change every second, where λ is the so-called radioactive constant. Then, dN , or $q - \lambda N$, particles of niton will be produced in the time, dt , so that the rate at which the niton accumulates in the system is equal to their rate of production less their rate of change, or

$$\frac{dN}{dt} = q - \lambda N \quad . \quad . \quad . \quad . \quad . \quad (3)$$

When this expression is integrated for the conditions $N = N_m$ when $t = \infty$; and $N = 0$ when $t = 0$, then, the quantity, N , of niton present in the system at the time will be

$$N = N_m(1 - e^{-\lambda t}) \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where N_m represents the maximum or equilibrium value, and λ is the decay constant 0.180 when t is expressed in days. All the time the niton and the active deposit are being formed by the radium, the occluded niton is decaying according to the law previously described. Hence, the quantity of niton reaches half-value in about 3.85 days; 75 per cent. in 7.70 days; 99.55 per cent. in 30 days; and in 50 days. 99.99 per cent. of the equilibrium value is present. The rate of production of niton is 1.24×10^{-9} c.c. per sec. per gram of radium. In 1910, the Radiology Congress at Brussels⁷ decided to call the amount of emanation or niton in equilibrium with a gram of pure radium a **curie**; smaller units are designated in the usual manner, thus the *millicuries* means the amount of emanation in equilibrium with

10 mgrms. of pure radium. A. Piccard and E. Stahel, and T. Nogier have raised the question of the constancy of the radioactivity of the standard tubes. E. A. Owen and B. Naylor discussed the measurement of the radium content of sealed tubes.

Since each α -particle emitted by radium becomes an atom of niton, and about 3.4×10^{10} α -particles are emitted per sec. per gram of radium, then the number, g , of atoms of niton formed per gram per sec. is 3.4×10^{10} . For equilibrium, dN/dt of (3) is zero, and hence, the number, N , of atoms of niton present per gram is $N = g/\lambda$; but $\lambda = 2.085 \times 10^{-6}$ per sec., hence, $N = 1.63 \times 10^{16}$. Under standard conditions one c.c. of gas contains 2.78×10^{19} mols., so that a curie of niton, supposed monatomic, occupies 0.59 c.mm. E. Rutherford obtained about 0.6 c.mm.; J. Danysz and W. Duane, 0.59 c.mm.; A. Debiere, 0.58 c.mm.; and R. W. Gray and W. Ramsay, 0.60 c.mm. Less accurate values were obtained by W. Ramsay and F. Soddy, and A. T. Cameron and W. Ramsay. For the action of radium emanation or niton on water, salt soln., gases, and organic products, see radium rays.

§ 8. The Products of the Rapid Decay of Radium Emanation—Radium-A to Radium-C

The radium from which the emanation has been abstracted loses about 75 per cent. of its radioactivity, and it then emits practically nothing but the α -rays; the β - and the γ -ray activities are almost completely lost. The radioactivity of radium gradually returns to its original value on standing. Hence, it is inferred that radium is constantly generating and storing the emanation, and that the emanation is constantly decaying. The rate at which the radium then regains its activity is equal to the rate at which the emanation loses its radioactivity. The radioactivity of normal radium is an equilibrium value because the rates of production and disintegration of the emanation are evenly balanced. While the dynamics of the transformation changes in radioactive matter seem to

follow similar laws to those which obtain in molecular changes with irreversible reactions, there is a marked difference in their behaviour towards changes of temp. and press. E. Rutherford¹ showed that the constants of the radioactive transformation are not affected by concentration, or the decomposition products. The effects of variations of *temperature* ranging from -186° to $+2500^{\circ}$ have been studied by W. Makower and S. Russ, H. W. Schmidt and P. Cermak, R. W. Forsyth, M. S. Curie and H. K. Onnes, W. Engler, etc. P. Curie and J. Danne observed the decay curves of the active deposits are influenced by changes of temp., but the work of H. L. Bronson, and A. S. Russell has shown that these results are due to differences in the volatilization or sublimation of the products when heated. E. Rutherford and J. E. Petavel noted that the high *pressure* developed in a bomb during the explosion of cordite—temp. 2500° , press. 1000 atm.—made no difference. A. Schuster, and A. S. Eve and F. D. Adams also showed that a press. of 2000 atm. had no appreciable influence. F. G. Donnan inferred that the energy given out on highly ex-energetic changes must be greater in strong than in weak *gravitational fields*. To test this, E. Rutherford and A. H. Compton subjected radioactive material to a centrifugal acceleration over 20,000 times that of gravity, and found no perceptible change over 1 part in 1000, the limit of the method of measurement. H. H. Poole showed that the corpuscular radiations have no effect on the changes; W. P. Jorissen and J. A. Vollgraff found that *cathode rays* have no result; P. Weiss and A. Piccard showed that an intense *magnetic field* has no effect; and W. Marckwald, and L. Bruner and E. Bekier observed no change in the presence of an *electric discharge*. H. S. Shelton has emphasized the fact that the indifference of radioactive changes to temp. and other physical conditions must be a relative phenomenon, and a consequence of the limited range of our resources. The highest temp. of our laboratories— 3000° —are feeble when contrasted with those ten times hotter, which prevail in the colossal furnaces revealed by stellar spectra of the hotter stars. Consequently, the indifference of radioactive changes to external conditions cannot be accepted as absolute. Suppose, he adds, that electricity were unknown and it was only possible to attain variations of temp. of a few degrees in our laboratories, then a large number of so-called compounds would be classed as elements, and the slow decomposition of many substances with the evolution of heat would appear as marvellous sources of energy, as unaccountable as radioactive changes are to-day.

The processes of decay and restoration cannot be influenced by any known controllable physical or chemical force; they are independent of the chemical form of radium—chloride, bromide, carbonate, sulphate, metal, etc.—all that can be done is to study the mode and measure the rate of change. Hence, rightly or wrongly, it has been inferred that the process is a property of the radium *atom* alone; that the radium atoms break down into atoms of the emanation; and the atoms of the emanation break down into a radioactive solid, the so-called **active deposit**, and helium gas. This recalls the step-by-step decomposition of potassium hypochlorite into potassium chlorate, perchlorate, and chloride as well as oxygen. By analogy with the evolution of heat which attends certain exothermal chemical reactions—e.g. the decomposition of ozone, $2\text{O}_3 \rightarrow 3\text{O}_2 + 68.2 \text{ Cals.}$ —it has been stated as a hypothesis that the origin of the energy of radioactive bodies is due to the decomposition of the atoms—a reaction accompanied by the liberation of charged particles. In the one case, the atoms re-form new and more stable combinations, and in the other case, the liberated particles are de-electrified and form helium. According to this hypothesis, a radioactive substance must have a more or less limited period of existence of life.

Radium emanation quickly breaks down into a new substance called radium-A, which has a half-life period of about 3 minutes, and passes into radium-B; and this, in turn, to radium-C; radium-C to radium-D; radium-D to radium-E; and radium-E to radium-F. Since the radioactivity due to radium-D, -E, and -F is negligibly small in comparison with that due to radium-A, -B, and -C—the initial radioactivity of the former being usually less than 10^{-5} of that of the latter—

E. Rutherford ² found it convenient to analyze the active deposit of radium produced by the condensation and decay of radium emanation into (i) the **deposit of rapid change** (radium-A, -B, and -C); and (ii) the **deposit of slow change** (radium-D, -E, and -F). Hence, radium normally contains all three products—radium proper, the emanating gas, and the active deposit. It is estimated that 25 per cent. of the radiations of normal radium belong to radium proper; 18 per cent. more of the α -rays belong to the emanating gas; and the remaining 57 per cent. to the active deposit. W. Mund studied the effect of an electric field on the distribution of the active deposit of radium. The rate of rise of γ -ray activity from radium emanation has been measured by F. P. Slater.

As previously indicated, the active deposit of radium was discovered by M. S. and P. Curie; and measurements of its radioactivity were made by E. Rutherford and H. T. Brooks, and P. Curie and J. Danne. The latter found that the radioactivity I of the active deposit at the time t secs. (disregarding the first 20 mins. so as to ensure the death of radium-A) could be represented by $I = I_0(4 \cdot 20e^{-0 \cdot 000413t} - 3 \cdot 20e^{-0 \cdot 000538t})$, where I_0 represented the initial radioactivity. E. Rutherford studied the decay of the activity of the deposit and found that the results could be explained on the assumption that three consecutive changes are involved, in which radium emanation passes directly to **radium-A**, the latter to **radium-B**, and that to **radium-C**₁ and **radium-C**₂.

Assuming that radium-A passes through a series of consecutive changes forming radium-B, radium-C, . . . it is required to find the concentrations of -A, -B, -C . . . respectively, at the end of a period of time t . If P atoms of a substance A change into another B during the time t , it has been shown, (1) and (2), that $dP/dt = -P$, or $P = P_0e^{-\lambda_1 t}$, where λ_1 is the radioactive constant for the change $A \rightarrow B$, and P_0 is the number of atoms of A originally present. Let dQ represent the increase in the number of atoms of B in unit time; then dQ is the number supplied by the change of the matter A less the number due to the change of the substance B into C, or

$$\frac{dQ}{dt} = \lambda_1 P - \lambda_2 Q \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where λ_2 is the radioactive constant for the change $B \rightarrow C$. Substituting $P = P_0e^{-\lambda_1 t}$, and integrating

$$Q = P_0 \frac{\lambda_1}{\lambda_2 - \lambda_1} (e^{-\lambda_1 t} - e^{-\lambda_2 t}) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

Similarly, when A changes to B, and B to C, if R represents the number of particles of C formed in the time t ,

$$\frac{dR}{dt} = \lambda_2 Q - \lambda_3 R \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where λ_3 is the radioactive constant for the change $C \rightarrow D$. Substituting for Q , and integrating,

$$R = P_0(k_1 e^{-\lambda_1 t} + k_2 e^{-\lambda_2 t} + k_3 e^{-\lambda_3 t}) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where

$$k_1 = \frac{\lambda_1 \lambda_2}{(\lambda_2 - \lambda_1)(\lambda_3 - \lambda_1)} \quad k_2 = \frac{\lambda_1 \lambda_2}{(\lambda_3 - \lambda_2)(\lambda_1 - \lambda_2)} \quad k_3 = \frac{\lambda_1 \lambda_2}{(\lambda_1 - \lambda_3)(\lambda_2 - \lambda_3)}$$

and so on for n products. For radium-A, radium-B, and radium-C, $\lambda_1 = 0 \cdot 2273$, $\lambda_2 = 0 \cdot 02585$, and $\lambda_3 = 0 \cdot 03554$ per min., so that $k_1 = 1 \cdot 1520$, $k_2 = 3 \cdot 0102$, $k_3 = -3 \cdot 1622$. Starting with one unit of radium-A, and none of radium-B or radium-C, the relative amounts of A, B, and C, obtained by calculation from equations (5) to (8), after the lapse of a specified time (minutes), are:

Time.	1	5	10	16	40	100	200	400
A .	0·7967	0·3210	0·1033	0·0261	0·0001	—	—	—
B .	0·2009	0·6313	0·7558	0·7176	0·4019	0·0851	0·0064	0·00003
C .	0·0029	0·0486	0·1238	0·2037	0·3079	0·1364	0·0145	0·00007

The corresponding curves are illustrated by Fig. 13. The numbers in clarendon type represent maxima in the curves. A. Piccard has discussed the drawing of the decay curves of radioactive substances. These and other relations have been discussed by E. Rutherford, and H. Bateman. They resemble analogous problems in the theory of ordinary consecutive reactions. Suitable modifications can be introduced when A, the primary source, is suddenly exhausted. H. Levy has suggested a criterion for finding the number, n , of radioactive transformations from a set of observations.

Values for the at. wt., the radioactive constants, the half-life period, and the average-life period of radium-A, -B, -C₁, and -C₂, were calculated by E. Rutherford, P. Curie and J. Danne, M. S. Curie, and H. L. Bronson :

	Emanation.	Radium-A.	Radium-B.	Radium-C.
Radioactive constant	2.085×10^{-4}	3.85×10^{-3}	4.33×10^{-4}	5.928×10^{-4}
Half-life period	1.25×10^{-4}	0.231	0.0258	0.0355
Average-life period	79.92×10^4	4.32	38.7	28.1
Atomic weight	222	218	214	214

Radium-A has such a short life that it can be but imperfectly isolated, observations must be made on it immediately after its production from niton. P. Curie and J. Danne found that the decay curves of the active deposit were much influenced by heating it to a high temp., and H. L. Bronson showed that these effects are not

FIG. 13.—Relative Distribution of A, B, and C after different Intervals of Time.

wire from the emanation, the activity of the subsequent products formed being, for such short exposures, usually negligible. After twenty to thirty minutes' exposure to the emanation, the quantity of radium-A attains equilibrium and does not further increase. But the amounts of radium-B and -C on the wire go on increasing with the time of exposure up to three or four hours. Obviously the shorter the time of exposure the purer is the radium-A deposited. Conversely with a wire which has been exposed any length of time to the emanation, no radium-A remains after twenty to thirty minutes from withdrawal, the activity at this stage being due to radium-B. Hence, without chemical treatment, radium-A alone or radium-B and -C, together, may be obtained at will by a suitable choice of the time of exposure to the emanation, and of the time elapsing after withdrawal from its influence.

If a negatively charged wire be kept in niton for a long time, the amount of radium-A which accumulates on the wire soon assumes the stationary state when the rate of production is equal to the rate of decay; the amounts of radium-B and radium-C continue increasing for many hours. F. von Lerch³ has reviewed the methods available for separating the radium-A, -B, and -C decay products.

W. Makower heated a wire to 900° in radium emanation, but was unable to collect radium-A, -B, and -C, whether the wire was charged negatively or positively. P. Curie and W. Duane stated that at 600°, radium-B could be volatilized freely from a plate coated with the active deposit, while radium C-remained behind.

due to the effect of temp. on the rate of transformation of the radioactive products; but were produced by the different volatilities of the three products. He found radium-A volatilized more readily than radium-B; and radium-B, more readily than radium-C. According to F. Soddy, if a negatively charged wire is exposed for a few seconds only in a relatively large quantity of radium emanation, the activity of the wire at first is almost entirely due to the α -rays of radium-A, and these decay to a very small value in a few minutes after withdrawal of the

The volatilization of radium-C was found by W. Makower to depend upon the surface on which it was deposited; thus, the volatilization of radium-C is appreciable at all temp., and all the radium-C passed off from platinum and nickel at 1200° , but from quartz, the volatilization was incomplete at 1300° . A. S. Russell, and H. Schrader have studied the nature of the surrounding gases on the volatilization. It is quite possible that oxides or other compounds may be formed. Many volatilized products deposit at a much lower temp. in ozone than in oxygen. The temp. required for the volatilization of radium-C in hydrogen is about 430° , and in oxygen about 1000° ; while radium-A is volatile in hydrogen at about 400° , and in oxygen at about 550° . According to H. L. Bronson, W. Duane, W. Makower, and A. S. Russell, radium-A volatilizes at about 900° , radium-B between 600° and 800° , and radium-C at 1100° . Hence it is possible to separate radium-B and radium-C by fractional volatilization.

O. Hahn and L. Meitner dissolved the active deposit in boiling hydrochloric acid, and allowed it to stand for three-quarters of an hour in order to allow all the radium-A to decay. When the acid liquid was agitated with animal charcoal, the radium-C is retained. The filtrate was treated with a barium salt and sulphuric acid, and the precipitated barium sulphate retained the radium-B. According to F. von Lerch, if cupric sulphate be added to the acid liquid, and a minute later, potassium hydroxide, radium-C was retained by the precipitate and radium-C remains in the filtrate. If lead nitrate be mixed with the hot acid liquid, and sulphuric acid added, radium-B is retained by the precipitate, and radium-C by the filtrate. If the acid liquid be electrolyzed with platinum electrodes, radium-C deposits on the cathode, while radium-B remains in soln. This shows that radium-C is rarer, *i.e.* less electropositive, than radium-B. F. von Lerch found that if a nickel or copper plate be dipped in the acid liquid, radium-C is precipitated while radium-B remains in soln. According to L. Meitner, the reaction is quantitative if a conc. boiling soln. be employed. T. Godlewsky found that in a neutral or feebly acid soln. of radium-B and radium-C, the latter, like bismuth, will be present in the colloidal form, possibly as a basic salt, the radium-B will be found in the filtrate. It will be observed that as soon as radium-B has been isolated it immediately begins to produce a fresh amount of radium-C by its own decay.

O. Hahn and L. Meitner, and W. Makower and S. Russ found that radium-B could be obtained in a pure state by recoil from radium-A, and that radium-C could be obtained from radium-B. The general method was to place an inactive plate charged negatively near a plate covered with active matter. The **recoil atoms** are concentrated on the negative plate in virtue of their positive charge. While the total amount of radium-C liberated by recoil is only about 1 in 6000, a considerable part of radium-A can be obtained by the recoil process. The collection of the recoil products on negatively charged plates proceeds most favourably in vacuo. It was once thought that radium-B is volatile at ordinary temp., but the apparent volatilization occurs only at the moment radium-B is being produced from radium-A; when all the latter has disappeared, there is no sign of the volatilization of radium below a red heat. The apparent volatilization at ordinary temp. is really a recoil effect due to the projection of radium-B from the active deposit by recoil at the moment the α -particle is expelled from the atom of radium-A. The distribution and range of recoil atoms was studied by K. T. Compton, etc.

B. H. Herszfinkel and L. Wertenstein⁴ measured the heat transformation of radium-B to radium-C. E. Rutherford showed that radium-A emitted only α -rays and radium-C, α -, β -, and γ -rays; while radium-B was at first thought to be rayless, but H. W. Schmidt found that radium-B emitted β -rays. These results were confirmed by K. Fajans and W. Makower, and F. von Lerch. H. G. J. Moseley and W. Makower showed that radium-B gives off as well readily absorbed γ -rays. The range and velocity of the α -particles of radium emanation are respectively 4.16 cms. and 1.69×10^9 cms. per sec.; the range of the α -particles of radium-A is 4.75 cms.; and the range and velocity of the α -particles of radium-C are 6.94 cms.,

and 1.92×10^9 cms. per sec. T. S. Taylor found the range of the α -particles of radium-C to be 6.93 cms. in air; 6.25 cms. in oxygen; 30.93 cms. in hydrogen; and 32.54 cms. in helium. The charge on the recoil atoms of radium-A and -B behaves similarly to that of the recoil atoms of niton, *q.v.* The decay curves of the α -rays of the active deposit were studied by H. L. Bronson. The curves of the β -rays were investigated by H. W. Schmidt, and H. L. Bronson, while K. Fajans and W. Makower showed that the β -rays from radium-B furnish two groups whose coeff. of absorption in aluminium are 91 cms. and 18 cms. The decay curves of the γ -rays were studied by H. G. J. Moseley and W. Makower. The recovery and decay curves were studied by E. Rutherford and J. Chadwick. According to H. W. Schmidt, the absorption coeff. of the β -rays of radium-B, in aluminium, are respectively 890, 80, and 13.1 cms.; E. Rutherford and H. Richardson gave for the absorption coeff. of the γ -rays of radium-B, in aluminium, 230, 40, and 0.51 cms. H. W. Schmidt gave for the absorption coeff. of the β -rays of radium-C in aluminium 1.3 and 53 cms.; and for the γ -rays, 0.115 cm. of aluminium, or 0.5 cm. of lead. H. Richardson also found a salt γ -radiation with an absorption coeff. of 40 cms. in aluminium. According to E. Rutherford and H. Robinson, and J. Chadwick, the magnetic spectra of the β -rays of radium-B and radium-C are very complex. H. G. J. Moseley and H. Robinson found that the β -rays of radium-B in equilibrium with a gram of radium, furnish 0.325×10^{15} pairs of ions corresponding with an energy of 1.71 cal. per hour; the γ -rays similarly give 0.084×10^{15} pairs of ions corresponding with 0.44 cal. per hour; the β -rays of radium-C likewise gave 0.64×10^{15} pairs of ions corresponding with 3.35 cal. per hour; and the γ -rays, 1.134×10^{15} pairs of ions or 5.96 cal. per hour. J. Szmidi found the distribution of energy in radium-B and radium-C in equilibrium with one another for the soft rays of radium-B; the hard rays of radium-B; rays from radium-C=1 : 45 : 639; or 0.01×10^4 , 0.49×10^4 , and 6.92×10^4 ergs per sec. C. D. Ellis studied the magnetic spectrum of the β -rays of radium-B.

It is generally assumed that radium-A is isotopic with polonium, and closely related with tellurium; that radium-B is isotopic with lead; and radium-C with bismuth. According to J. Patkowsky,⁵ the radium atom derived from radium emanation deposits on different metals in approximately the order of the electrochemical series; thus, 14 per cent. more deposits on silver than on aluminium. According to E. Ramstedt, radium-B and -C deposited on glass surfaces from the emanation give more regular solubility results than when deposited on gold or platinum. Only about one-half (mean 0.52) of the active deposit on a glass surface is readily dissolved; the other half is not dissolved at all on boiling with acid, but with gold and platinum the soluble part amounts to 60–70 per cent. This is explained by the recoil of the radium-B particle in its formation from radium-A, driving it into the surface. For radium-B deposited on a plate by projection from a radium-A surface the whole is soluble. Radium-C is soluble in the common acids, less so in alkaline liquids and in water, and very little in organic solvents. Radium-B dissolves more quickly than radium-C in water and acids, especially when dil., less quickly in alkaline liquids and very little in organic solvents. Radium-A is more soluble than radium-B and -C, and dissolves even in organic solvents, especially carbon disulphide, which confirms its position in the sulphur family of elements. The speed of soln. increases with the temp. of the solvent, and S. Arrhenius's formula applies approximately. It was found by depositing the active material on plates of gold and platinum previously saturated electrolytically with hydrogen and oxygen that oxygen enormously diminishes the solubility, especially of radium-C, whilst hydrogen diminishes the relative speed of soln. of radium-A. The influence of oxygen on solubility is analogous to that on volatility. A. Fleck discussed the isotopy of radium-B and actinium-B, and of radium-C, thorium-C, actinium-C, and bismuth.

Radium-C emits α -, β -, and γ -rays, and since most substances emit either α -rays or β - and γ -rays, O. Hahn and L. Meitner⁶ tested by the recoil method the nature of radium-C deposited on nickel from an acid soln. of the active deposit. They

obtained evidence showing that radium-C is a complex product which deposits a short-lived substance **radium-C₂** on a negatively charged plate. K. Fajans found radium-C₂ separated by recoil, emitted β -rays but no γ -rays. The β -rays had approximately the same penetrating power as those emitted by radium-C. The amount of radium-C₂ obtained by recoil was small and possessed only about $\frac{1}{6000}$ th of the β -ray activity of the parent radium-C. Radium-C produced radium-D by recoil in approximately the amount required for a vigorous α -ray recoil. The small amount of radium-C₂ so obtained indicated that it could not be a direct product of radium-C. K. Fajans and W. Makower further showed that radium-C₂ could not be in the main line of descent from radium-C₁, but must be a side product. Hence radium-C₁ breaks up in two ways; about 99.97 furnishes radium-D, with the emission of β - and γ -rays, and a small fraction, about 0.03 per cent., with the emission of α -rays, furnishes radium-C₂. The decay products from the emanation are therefore:

The transformations along the side chain radium-C₂ have not been closely followed. The at. wt. of radium-C₂ is probably 210; the half-life period, 1.38 mins.; the average life period, 1.99 mins.; the radioactive constant $\lambda = 0.495 \text{ min. or } 8.4 \times 10^{-3} \text{ secs.}$; the absorption coeff. for the β -rays is 13 and 53 cms. of aluminium. In its decay, radium-C₁ gives α -rays, radium C₂ gives off β - and γ -rays; the initial velocity of the β -rays is 2.4×10^{10} to 2.94×10^{10} cms. per sec. E. Albrecht obtained for the velocity-ratio $\text{Ra-C}_2 : \text{Ra-C} = 0.0004$. C. D. Ellis, and J. Neukirchen measured the wave-lengths of the γ -rays from radium-C.

§ 9. The Products of the Slow Decay of Radium Emanation—Radium-D to Radium-F

M. S. Curie,¹ F. Giesel, and E. Rutherford found that the activity of the deposit obtained by exposing a body to radium emanation does not all disappear when removed from the emanation; rather does a small residual activity remain, the magnitude depending on the quantity of the emanation, and the time of exposure. The α -ray activity of the matter remaining after the decay of the products of the rapid transformation gradually increases with time and after 300 days the curve approaches a maximum value; and the β -ray activity approaches a maximum in about 40 days. The phenomena are interpreted to mean that the residual active matter consists of the products of three successive changes—radium-D, radium-E, and radium-F. Radium-D gives off slow β -rays, and very soft γ -rays; radium-E both β -rays and weak γ -rays; and radium-F gives off α -rays. K. Fajans showed that radium-D is derived directly from the decay of radium-C; the former can be obtained by recoil from the latter.

J. Elster and H. Geitel observed that the lead separated from pitchblende was markedly reactive, owing, it was said, to the presence of small quantities of radium and polonium; K. A. Hofmann and E. Strauss, however, concluded that the lead separated from uranium minerals contained a new radioactive substance which they called *radio-lead*—a similar term, *radium lead*, was later applied to radium-G. The preparation of radio-lead from uranium minerals (not autunite) described by K. A. Hofmann and co-workers is as follows:

The chloride or nitrate soln. is stirred with 0.02 eq. of sulphurous or sulphuric acid; after standing 14 days, the mixture is filtered, and the precipitate washed. The radio-lead is also separated from polonium by the fractional crystallization of the nitrate; or by decomposition with sodium thiosulphate; or by the electrolysis of the nitrate in warm dil. nitric acid. In another process, the chloride is digested for 10 hrs. at 35°, with an equal weight of fuming hydrochloric acid free from sulphuric acid; the soln. evaporated to $\frac{1}{2}$ th of its volume; made up to one-fourth of its original volume with hot water.

The filtrate containing about half per cent. of free hydrochloric acid, is treated with hydrogen sulphide, and the sulphide washed with dil. hydrochloric acid and then with ammonium sulphide.

K. A. Hofmann's radio-lead was shown by E. Rutherford to contain radium-D, radium-E, and radium-F; and, when freshly prepared, **radium-D**, as the primary radioactive constituent. Radium-D is almost rayless, and when purified, as first described, radio-lead appears inactive; but radioactivity is generated in the course of time owing to the partial decay of radium-D into radium-E and radium-F. The chemical and physical properties of radium-D and lead are so similar that, in spite of the attempts of K. A. Hofmann and V. Wölff, F. Paneth and G. von Hevesy, B. Szilard, and H. Herschinkel no satisfactory method has been found for concentrating the radioactive constituent, radium-D, from the lead.

Among the unsuccessful methods tried are (i) by precipitation of chloride soln. at 100° with dil. sodium thiosulphate and with hydrochloric acid; (ii) by precipitation with quadrivalent lead compounds, by precipitation of a lead chloride soln., sat. with chlorine, with ammonium chloride, whereby plumbichloride is precipitated; by passing sulphur

dioxide through a soln. sat. with lead chloride and hydrogen chloride, whereby the lead chloride is fractionally precipitated; and by precipitation of lead dioxide by addition of hydrogen dioxide or bromine water to a soln. of lead hydroxide in sodium hydroxide, or of bromine water to lead acetate; (iii) by adsorption methods, as by precipitation of barium sulphate or silicofluoride in lead nitrate soln., or barium chloride in a lead chloride soln. by saturating with hydrogen chloride; also by separating iron from lead chloride soln. by the acetate precipitation, by adding potassium permanganate and alcohol to lead chloride soln., and by boiling the latter with flowers of sulphur; (iv) by distillation of lead chloride in carbon dioxide at 1000° ; (v) by electrolysis in soln., under varying conditions, so that part of the lead separates on the cathode and part on the anode as dioxide, and of molten lead chloride, pure or mixed with potassium chloride; (vi) by dialysis of lead nitrate through parchment paper or animal membrane and diffusion of lead chloride soln.

It is therefore inferred that the radium-D and lead are isotopic. According to F. Soddy, common commercial lead contains traces of radium-D which makes lead more radioactive than most of the other metals. If lead is desired free from radioactive products, old lead should be used, since the active constituents will presumably have decayed.

A. T. Cameron and W. Ramsay found that after a large quantity of purified emanation had been allowed to decay in a small capillary, a black, sub-metallic film appeared, and this was ascribed to the decay of the emanation into radium-D. This is the simplest method of purifying radium-D free from elements other than those belonging to the radium series. Another source of radium-D is in old radium preparations kept in a solid state, or under such conditions that the emanation is retained; radium-D steadily accumulates in the system until about 8 mgrms. of radium-D are present per gram of radium; and it can be separated from radium-E, and radium-F, by precipitation with sulphuric acid; the radium-D is separated from radium by adding a little lead and separating the lead by hydrogen sulphide—radium-D follows the lead.

The at. wt. of radium-D is about 210. G. von Hevesy and F. Paneth found the diffusion constant of radium-D is characteristic of that of a bivalent element being 0.65 sq. cm. per day. E. Rutherford found radium-D is volatile at a high temp. The rays emitted by radium-D are so feeble in comparison with those of radium-E, that E. Rutherford at first thought radium-D is rayless; O. von Bayer, O. Hahn, and L. Meitner, however, detected feeble β -rays with an initial velocity of 2.31×10^{10} cms. per sec.; the β -rays consists of two homogeneous beams emitted with 0.31 and 0.37 of the velocity of light, or with velocities 0.99×10^{10} cms. per sec. A. F. Kovarik showed that the absorption coeff. of the β -rays in aluminium is 130 cms. $^{-1}$. L. Meitner thinks this too large and gives 5500 cms. $^{-1}$. Radium-D thus furnishes the softest known γ -rays. L. Meitner studied the γ -rays from radium-D. E. Rutherford and H. Richardson found evidence of feeble γ -rays with absorption coeff. in aluminium of 45 and 0.99 cms. $^{-1}$. The transformation of radium-D into radium-E is too slow to permit direct observations except over a period of years. E. Rutherford estimated its half-life period to be 40 yrs.; and S. Meyer and E. von Schweidler 37.5 yrs. Later determination by E. Rutherford, R. Thaller, M. S. Curie, and G. N. Antonoff gave for the half-life period, 16.5 yrs.; for the average-life period, 23.8 yrs.; and for the radioactive constant $\lambda = 0.0433$ yr., 1.18×10^{-4} days; 4.94×10^{-6} hrs.; 8.22×10^{-8} mins.; or 1.37×10^{-9} secs. R. W. Lawson found that if polonium is deposited by electrolysis on a clean metal foil it is found subsequently that, at normal press. and in vacuo, surrounding objects become active also. The phenomenon can be explained on the supposition that aggregates of polonium atoms are carried off from the active surface and deposited on neighbouring surfaces.

The spectrum of radium-D has not been satisfactorily determined. E. Demarçay attributed the lines 3659.6 and 4116.8 in the spectrum of radio lead to radium-D, but the former possibly belongs to molybdenum, and the latter to vanadium. G. von Hevesy and F. Paneth inquired whether the inseparability of lead and radium-D is due to our ignorance of a suitable method, or to the identity of the properties of the two elements. It was inferred that two elements are chemically

identical, *i.e.* isotopic, when they are electrochemically replaceable. They found that cells of radium-D dioxide and nitrate and of lead dioxide and nitrate gave the same difference of potential, and that ions added to both cells gave the same change of potential.

The growth of the β -ray activity of radium-D, and the subsequent appearance of α -rays, shows that radium-D probably decays into **radium-E**. When a mixture of radium-D, radium-E, and radium-F is heated to over 1000° , E. Rutherford found that the greater part of the first and the last are volatilized while radium-E remains. The *β -strahlende Bestandteil* of K. A. Hofmann's *radio-lead*, is identical with radium-E. S. Meyer and E. von Schweidler thought that radium-E is a complex of radium-E and radium-E₂, because it furnished two β -ray products with half-life periods of 4.8 and 6.2 days. It was said that at a red heat radium-E₁ is volatile, and that radium-E₂ is not volatile; and that when an electro-deposited film is treated with hot acetic acid, radium-E₁ dissolves while radium-E₂ remains insoluble. G. N. Antonoff, however, showed that there is only one β -ray product with a half-life period of about 5 days. F. Giesel separated a β -ray product with a half-life period of 6 days from polonium, and he called it *β -polonium*—this is taken to have been radium-E. In its chemical behaviour, radium-E behaves like bismuth with which it is isotopic.

According to S. Meyer and E. von Schweidler, if a soln. of lead chloride containing radium-D, radium-E, and radium-F be boiled with nickel, palladium, iridium, or silver foil, radium-E is alone deposited on the metal. If much lead chloride be present, it is advisable to first crystallize out the lead salt. In old radium preparations containing radium-D, radium-E, and radium-F, the first named can be precipitated with the radium sulphates; radium-E and radium-F remain in soln. When a soln. of a lead salt, containing radium-E and radium-F, is electrolyzed with about 4 microamps., *i.e.* 4×10^{-6} amps. per sq. cm., radium-F is first deposited on the cathode, and on increasing the current density to 10 microamps. per sq. cm., a mixture of radium-E and radium-F is precipitated; and with a current of 10^{-4} amp. lead (and radium-D, if present) is deposited. This is in accord with *F. von Lerch's rule*: the successive products of a disintegration series is accompanied by a regular increase in the electro-negative character, the successive products being each electrochemically nobler than the last, and therefore more easily deposited in electrolysis. As a rule, the successive products of the disintegration series become more volatile, and more soluble in acids.

G. von Hevesy and F. Paneth found that the diffusion coeff., 0.45 sq. cm. per day, agrees with the assumption that radium-E is trivalent, and belongs to the bismuth family. According to S. Meyer and E. von Schweidler, and E. Rutherford and H. Richardson, radium-E gives off β rays which have an absorption coeff. in aluminium of 43 cms.^{-1} ; the magnetic spectrum gave no sharp separations; the average velocity of the β -rays is 2.3×10^{10} cms. per sec. The γ -radiations are extraordinarily feeble, being less than 0.3 per thousandth of the β -radiations, and have an absorption coeff. resembling that of radium-D. J. A. Gray found that the primary γ -rays of radium-E are able to excite characteristic radiations in elements of at. wt. between silver and didymium. The half-life period has been estimated by E. Rutherford, F. Giesel, J. Danysz, G. N. Antonoff, M. S. Curie, and L. Meitner; the best representative value is 5 days; while the average-life period is 7.2 days. The radioactive constant is $\lambda = 1.66 \times 10^{-6}$ secs., 9.96×10^{-5} mins., 5.95×10^{-3} hrs., 0.1429 day, 52.19 yrs.

The first radioactive substance separated in 1898 by M. S. Curie from uranium minerals was named **polonium** after the native country of M. S. Curie. It appeared with bismuth in the precipitate obtained with hydrogen sulphide during the isolation of radium (*q.v.*). W. Marekwald obtained a radioactive precipitate by immersing a polished bismuth plate in a soln. prepared from uranium minerals; the precipitate also contained tellurium and the radioactive constituent was consequently called *radio-tellurium*; S. Meyer and E. von Schweidler also called it *radioactive bismuth*.

These products as well as the α -ray product in radio-lead and the α -ray stage in the decay of radium-E are all thought to be identical; their half-life periods are the same within the limits of experimental error. When it is desired to emphasize the fact that polonium is a decay product of radium-E, it is called **radium-F**. A. Fleck discussed the origin of radium-F.

M. S. Curie showed that the radioactivity of the sulphides precipitated from acid soln. of pitchblende by hydrogen sulphide, is due to the presence of polonium. There are also present sulphides of bismuth, copper, lead, and a little antimony and arsenic. She employed the following process for isolating the active sulphide:

The soln. made strongly acid with hydrochloric acid are precipitated with hydrogen sulphide; the sulphides thus precipitated are very active, and are employed for the precipitation of polonium; there remain in the soln. substances not completely precipitated in presence of excess of hydrochloric acid (bismuth, lead, antimony). To complete the precipitation, the soln. is diluted with water, and treated again with hydrogen sulphide, which gives a second precipitate of sulphides, much less active than the first, and which have generally been rejected. For the further purification of the sulphides, they are washed with ammonium sulphide, which removes the last remaining traces of antimony and arsenic. They are then washed with water and ammonium nitrate, and treated with dil. nitric acid. Complete soln. never occurs; there is always an insoluble residue, more or less considerable, which can be treated afresh if it is judged expedient. The soln. is reduced to a small volume and precipitated either by ammonia or by excess of water. In both cases the lead and copper remain in soln.; in the second case, a little bismuth, scarcely active at all, remains also in soln.

The precipitate of oxides or basic nitrates is fractioned by dissolving the precipitate in nitric acid and adding water to the soln. until a sufficient quantity of precipitate is formed. It must be borne in mind that sometimes the precipitate does not at once appear. The precipitate is separated from the supernatant liquid, and re-dissolved in nitric acid, after which both the liquids thus obtained are re-precipitated with water, and treated as before. The different fractions are combined according to their activity, and conc. is carried out as far as possible. In this way is obtained a very small quantity of a substance of which the activity is very high, but which, nevertheless, has so far only shown bismuth lines in the spectroscope. There is, unfortunately, little chance of obtaining the isolation of polonium by this means. The method of fractionation just described presents many difficulties, and the case is similar with other wet processes of fractionation. Whatever be the method employed, compounds are readily formed which are absolutely insoluble in dil. or conc. acids. These compounds can be re-dissolved only by reducing them to the metallic state, e.g. by fusion with potassium cyanide. Considering the number of operations necessary, this circumstance constitutes an enormous difficulty in the progress of fractionation.

In addition to the conc. of the active sulphide by precipitation with hydrogen sulphide from a conc. soln. in hydrochloric acid—polonium sulphide is less soluble than those of bismuth or lead—and the precipitation of the basic nitrate with water, whereby polonium accumulates in the precipitate, M. S. Curie sublimed the mixed sulphides in vacuo, and found that polonium sulphide is more volatile than that of bismuth. W. Marckwald treated the hydrochloric acid soln. of radioactive bismuth chloride from pitchblende with metallic bismuth or antimony, and found the radioactive matter deposited as a black film. This film is nearly all tellurium since pitchblende contains about 0.01 per cent. of tellurium. To remove tellurium, the metal was dissolved in hydrochloric acid, and the tellurium precipitated by hydrazine hydrochloride; the operation was repeated a number of times. The filtrate containing bismuth, tin, selenium, and tellurium was conc. by evaporation, treated with a few drops of stannous chloride, and digested on the water-bath. The precipitate was again dissolved in nitric acid, evaporated with hydrochloric acid to drive off the nitric acid, and the soln. treated with sulphur dioxide. The precipitate was again dissolved in nitric acid, evaporated to dryness, and warmed with ammonia. The amount of residual radio-tellurium corresponded with 3 mgrms. per 15 tonnes of pitchblende. W. Marckwald also found that when plates of bismuth, copper, or silver are immersed in the hydrochloric soln., nearly all the polonium is deposited on the plates. M. S. Curie and A. Debierne also, instead of treating the hydrochloric acid soln. with hydrogen sulphide, introduced an iron plate and found copper, bismuth, lead, arsenic, antimony were precipitated. The precipitate was dissolved in hydrochloric acid, and treated with copper plate; this was again dissolved

in acid, and treated with stannous chloride as indicated above. H. M. Plum employed a similar process in the separation of polonium from carnotite. According to F. Paneth, the separation of radium-E and polonium from radio-lead by dialysis is due to the fact that radium-E and polonium are both easily hydrolyzed in aq. soln. The basic salts or hydroxides thus formed remain in soln. as colloids, and consequently do not pass through the membrane with lead and radium-D. If, on the other hand, a nitric acid soln. of radioactive lead is dialysed, there is no separation. G. von Hevesy found that the more basic radioactive products dissolve more rapidly in neutral, alkaline, or weakly acid soln. than the nobler ones.

The electrolytic separation of radium-D and radium-E in radio-lead by S. Meyer and E. von Schweidler's process has already been described. G. von Hevesy and F. Paneth studied the decomposition potential of polonium in $10^{-8}N$ -soln., and N -soln. with respect to nitric acid and gold electrodes. Gold was employed because it has no special affinity for polonium, which is deposited, from vapour, preferentially on platinum and palladium. Nitric acid removes all but 0.5 per cent. of the polonium electrochemically deposited on gold, but leaves 13 per cent. in the case of platinum. Under similar conditions the ratio of the amounts of polonium

FIG. 14.—Decomposition Potential of Polonium.

deposited on gold and platinum electrodes are as 2 : 3. The polonium used was estimated to be in $10^{-8}N$ -soln. By gradually increasing the current strength the cathode and anode potentials were gradually raised. A sudden increase was noted in the cathode at $E_{Hg}=0.35$ volt and on the anode at $E_{Hg}=1.05$ volts, Fig. 14. The anodic deposition is to be explained, as with manganese and lead, as being due to the deposition of a peroxide of polonium. Diffusion experiments show that polonium is bivalent, and the normal potential of polonium, calculated from the decomposition potential at $10^{-8}N$, is $0.35 + 8 \times 0.028 = 0.57$ volt. This lies near the normal potential of silver. The calculated normal potential of polonium peroxide, in

$10^{-3}N$ -nitric acid, is $+0.89$ volt, that of lead being 0.82 volt. By varying the conditions it is possible to confine the deposition of polonium to the anode or cathode at will, and the fractional deposition of polonium as peroxide can be used to separate it from metals, such as gold, mercury, etc., which are not anodically deposited. Owing to the tendency to form colloidal soln., neutral or weak acid soln. are to be avoided, $10^{-1}N$ -nitric acid being suitable.

F. Paneth and G. von Hevesy extracted polonium from the lead nitrate derived from pitchblende in the following manner. The yield was about 80 per cent. The hot sat. soln. of the lead nitrate is left to crystallize, the mother liquor is separated by centrifuging, and after being slightly diluted is electrolyzed with platinum electrodes and a feeble current, a few mg. of bismuth being added to diminish the separation of radium-E. The cathode potential must not exceed -0.8 volt, which corresponds, in the soln. described, with 0.16 milliamp. per sq. cm., but if freedom from radium-E is desired, a potential of -0.5 volt or 0.4 milliamp. per sq. cm. may be used. Stirring is advantageous both in electrolysis and also on deposition on copper, which is an equally good method. If polonium free from lead and radium-D, but not from radium-E, is required, so much conc. nitric acid is added that lead is no longer cathodically deposited. Under these conditions most of the polonium can still be separated at the cathode. By volatilization at 1000° , all but 0.1 per cent. of the polonium may be removed from the electrodes, which is difficult to do by boiling with acids. The polonium vapour condenses preferably on palladium and platinum, in special degree on the former, rather than on gold, copper, nickel, or the walls of a quartz tube.

Old preparations of radium furnish radium-F: (i) by S. Meyer and E. von Schweidler's electrolytic process; or (ii) by treating the acidified soln. with hydrogen sulphide; on filtration, an invisible deposit of polonium sulphide will be found on the filter paper; or (iii) by dipping a piece of platinum or bismuth foil in the soln. when the polonium deposits on the metal. Radium-F can also be obtained from radium emanation which has stood for some months in a glass vessel. The excess of emanation is removed; the film deposited on the glass walls is dissolved in sulphuric acid; and the polonium precipitated by introducing a piece of bismuth foil in the soln.

The at. wt. of polonium is about 210. A. Muszkat, and H. Herschfinkiel consider polonium and radium-A are isotopic. The chemical properties of polonium are closely related to those of bismuth, and still more closely to those of tellurium; but these elements are not isotopic. Polonium stands below tellurium in the vertical column of the periodic table when the elements are arranged according to their atomic numbers. The compounds are easily hydrolyzed, reduced, and electrolyzed. In analysis, polonium follows bismuth, from which it is separated as described above. F. Paneth, and R. W. Lawson prepared volatile *polonium hydride* by passing hydrogen over electro-deposited polonium heated to 700° – 900° in a quartz tube; and F. Paneth, by allowing electro-deposited polonium to act on ionized hydrogen. Polonium can be alloyed with palladium and platinum; and, according to G. Costanzo, palladium occludes radium-A which is isotopic with polonium. According to F. Paneth, polonium and radium-E are colloidal in neutral soln., radium-D in ammoniacal soln. While radium does not assume the colloidal form in neutral or alkaline soln., polonium migrates towards the cathode in acid soln., and towards the anode in ammoniacal soln. G. von Hevesy and F. Paneth found the coeff. of diffusion, 0.76 sq. cm. per day, in feebly acid soln., is characteristic of a bivalent metal, but in alkaline soln., say $\frac{1}{2}N-NH_3$, the coeff. is 0.19 sq. cm. per day.

According to P. Curie, O. Wigger, B. Kucera and B. Masek, M. Levin, S. Meyer and co-workers, W. Michl, H. Gieger and J. M. Nuttall, E. Rutherford, and R. W. Lawson, radium-F emits α -particles with a range of 3.77 cms. in air at 15° , and with a velocity 1.61×10^9 cms. per sec. T. S. Taylor found at 15° a range of 3.77 cms. in air, 3.43 cms. in oxygen, 16.83 cms. in hydrogen, and 17.52 cms. in helium. I. Curie found the velocity of the α -rays of polonium to be 1593×10^9 cms. per sec. A. Muszkat and L. Wertenstein studied the fluctuations of the α -radiations of polonium. M. S. Curie showed that the α -rays from polonium produce chemical and physical effects like those of radium. A milligram of polonium, however, emits as many α -particles as 5 grms. of radium. The α -rays are homogeneous, and no β -rays are emitted. The half-life period, determined by M. S. Curie, S. Meyer and E. von Schweidler, F. Giesel, H. Becquerel, E. Rutherford, W. Marckwald and H. Greinacher, J. W. Waters, E. Regener, and R. Girard, averages 136 days; and the average-life period, 196 days. The radioactive constant, $\lambda = 5.88 \times 10^{-8}$ secs.; 3.528×10^{-6} mins.; 2.12×10^{-4} hrs.; 5.078×10^{-3} days; or 1.855 yrs. M. S. Curie found that if θ denotes the mean interval between the emission of α -particles by polonium, the fraction of the total intervals of greater duration than τ , is $e^{-\theta/\tau}$. She found λ to be 0.00496 day $^{-1}$, corresponding with the average life 202 days, and the period of half-change 140 days. D. Bose found that about one in 1038 α -particles of polonium show a branching path in hydrogen gas. T. R. Wilkins studied the ionization produced by the α -rays from polonium. M. S. Curie and A. Debierne extracted from several tons of pitchblende 2 mgrms. of radioactive matter containing about 0.1 mgrm. of polonium. The spectrum showed the presence of many elements and of new lines 4642.0 , 4170.5 , 3193.6 , and 3652.1 , which were ascribed to polonium. Other lines were described but their connection with polonium is doubtful. The new lines are being periodically examined to find if they disappear and give place to the spectral lines of lead, suspected to be the product of the decay of radium-F. The saturation current produced between two infinitely extended plate electrodes by radium-F has been studied by G. Richter. Every α -particle from polonium

was observed by H. Geiger and A. Werner to produce a scintillation when it strikes a crystal of willemite. F. Paneth found evidence of the formation of a **polonium hydride** by the action of magnesium powder on soln. of salts of that element, and the compound was studied by F. Paneth and A. Johannsen.

§ 10. The Progenitors of Radium

Uranium has a higher at. wt. than any other element; and it is also characterized by an unusually large number of spectral lines. F. Exner and E. Haschek,¹ for instance, record 4940 lines in the arc-spectrum, and 5655 lines in the spark-spectrum. These facts support the assumption that uranium is not a homogeneous element, and this view is in harmony with the evidence derived from a study of the radio-activity of this element. The early experiments of M. S. Curie had demonstrated that the radioactivity of uranium is an atomic property in that it is dependent only on the amount of that element present, and is not affected by the nature of other inactive elements with which it may be combined.

The genetic relationship between uranium and radium is emphasized by the fact that (i) Radium and uranium always occur together, and the two elements are not sufficiently common for this to be due to mere chance; and that, as previously shown, (ii) the proportion of radium to uranium in old uraniferous minerals is

almost invariable, being nearly 1 : 3,400,000. Given the amount of uranium in a mineral the amount of radium can be computed from this ratio $U : Ra = 3.4 \times 10^{-7}$. This approximate constancy is clearly the result of an equilibrium between production and decay. The supply of radium is regulated by its relative rates of formation and degradation; and when the speeds of the opposing reactions are balanced, the ratio radium : uranium must be constant. It is interesting to observe in this connection radium has been shown to be a disintegration product of the radioactive elements—*vide supra*; and that a very small amount of helium is always found occluded in uraniferous minerals. This subject has been investigated by R. J. Strutt, B. B. Boltwood, E. Rutherford, J. A. Gray, R. J. Moss, M. S. Curie, etc. Assuming that no helium escapes, the small amount found in a given rock will be a measure of the time which has elapsed since the birth of that particular sample, but this gas must be constantly leaking into the atm., and, consequently, the age so computed will be a minimum age of the mineral, for the mineral may be older, but not younger than the age so computed. Hence, by determining the relative amounts of uranium and helium in a mineral, its minimum age can be estimated. In this way, R. J. Strutt estimated that it requires eleven million years to produce one c.c. of helium per gram of uranium.

Under ordinary conditions, uranium and all its salts—presumably freed from radium—are radioactive; the freshly prepared uranium products give only α -rays, but β -rays are slowly developed, and increase up to an equilibrium value which is attained in 6 to 12 months. Some γ -rays are also given off. W. Crookes² showed that uranium could be prepared photographically inactive, and the whole of the activity concentrated in a small residue free from uranium, by precipitating a soln. of a uranium salt with ammonium carbonate. On dissolving the precipitate in an excess of the reagent, an insoluble residue remained. This was filtered off, and was found to be many hundreds of times more active photographically than the uranium from which it had been separated. It contained a small quantity of what was called **uranium-X** to distinguish it from uranium or uranium proper. F. Soddy and A. S. Russell say that the success of W. Crookes' process depends on the presence of small quantities of iron and aluminium, for the uranium-X attaches itself to the insoluble impurities. If highly purified uranium be employed, it is best to add a little ferric salt so as to fix the uranium-X. This process was also used by H. Schlundt and R. B. Moore, and by O. Hahn and L. Meitner. S. J. Lloyd separated the uranium-X from the iron, by dissolving the insoluble mass in conc. hydrochloric acid, and extracting the soln. with ether sat. with hydrogen chloride. The uranium-X remains in the aq. layer. In the ammonium carbonate process, F. Soddy recommended dissolving the precipitate in acid, and pouring the soln. into very conc. aq. ammonium carbonate. The soln. can be fractionally precipitated by boiling. According to the nature of the impurities, the uranium-X comes down sharply and definitely with one of the fractions, usually in the middle of the series. Uranium freed from uranium-X emits only α -rays; uranium-X is responsible for the β - and γ -rays.

T. Godlewsky found that the nitrate of uranium-X is more soluble in water than that of uranium, $UO_2(NO_3)_2 \cdot 6H_2O$, so that on crystallization uranium-X gradually accumulates in the mother liquid. Hence, if a layer of crystals of the nitrate be heated and allowed to cool slowly, crystallization begins at the bottom, and the uranium-X accumulates in the surface layers. In the course of time, the uranium-X gradually diffuses from the surface layers, and becomes uniformly distributed. This accounts for the anomalous changes in the β -ray activity of uranium observed by S. Meyer and E. von Schweidler. This method of isolating uranium-X was employed by F. Soddy and A. S. Russell, and B. Szilard; they found that if a hot soln. of sp. gr. 2.05 be allowed to cool, about two-thirds of the salt crystallizes out, and the mother liquid contains about six-sevenths of the total uranium-X. The uranium-X can thus be rapidly conc. by successive crystallizations.

According to W. Crookes, if crystals of uranium nitrate be shaken with aq.

ethyl ether, the lower aq. layer contains uranium which gives the α - and the β -rays; while the upper ethereal layer contains uranium which gives the α -radiations only. Uranium-X thus accumulates in the aq. layer. The extracted uranium regains its power of emitting β -rays and attains a maximum in 6-12 months. A second quantity of uranium-X can be extracted from restored uranium, and so also a third and fourth extraction can be made; and, so far as we can guess, the extraction, restoration, and re-extraction can be repeated an indefinite number of times, that is, until all the uranium has been transformed into uranium-X. Hence, it seems impossible to avoid the inference that **uranium is continuously and spontaneously decomposing into uranium-X and α -particles of helium**. R. B. Moore and H. Schlundt, and V. F. Hess, employed a number of solvents—methyl or ethyl ether; acetone; methyl, ethyl, or amyl alcohol; or methyl or ethyl acetate. They said that acetone and methyl acetate gave the best results; and that the solvents work better if a little iron salt is mixed with the uranium salt. O. H. Göhring combined the ammonium carbonate and the ether processes.

500 grms. of freshly powdered uranyl nitrate was dissolved in 500-600 c.c. of ether; the aq. layer contained the uranium-X and was separated from the ethereal layer by a separating funnel. $\frac{1}{4}$ N-ammonium carbonate was added to the aq. soln. until a precipitate was formed. The precipitate was dissolved in an excess of the ammonium carbonate soln. The insoluble iron or thorium hydroxide was allowed to stand an hour, and filtered from the uranium soln. The whole operation occupies about 2 hrs., and the yield of uranium-X is about 98 per cent.

H. Becquerel, and M. Levin showed that uranium-X is entrained with barium or calcium sulphate precipitated in the soln.; and H. Becquerel, M. Levin, V. F. Hess, and A. Ritzel found that when the uranium salt soln. is boiled with animal charcoal, or soot obtained by burning naphthalene, the uranium-X is adsorbed by the solid; and the carbon can then be removed by ignition. According to A. Ritzel, if a thorium salt be present, the uranium-X cannot be separated therefore by charcoal—presumably thorium and uranium-X are physically and chemically isotopic. A. Ritzel showed that there is a definite equilibrium constant in the partition of the uranium-X in the soln. and in the solid; and A. J. Berry obtained an analogous result with barium sulphate in place of carbon. A. C. Brown found the adsorption of uranium-X by basic ferric acetate is proportional to the conc. A. Fleck discussed the isotopy of uranium-X, thorium, and radactinium.

B. Keetmann added thorium to the uranium soln. and precipitated the acid soln. of uranium-X and thorium as fluorides by adding hydrofluoric acid. G. N. Antonoff added a lanthanum salt in place of a thorium salt, and afterwards precipitated the latter with sodium thiosulphate. A. Ritzel also recommended separating uranium-X by adding some sodium phosphate to the strongly acid soln., and neutralizing with dil. sodium hydroxide. A part of the uranium gradually separates as phosphate, which contains all the uranium-X. The phosphate is dissolved in sulphuric acid, some cerium salt is added, and then hydrofluoric acid. The uranium-X is precipitated with the fluorides. K. Fajans and O. H. Göhring obtained good results with this process.

O. Hönigschmid recommended purifying uranium from other radioactive substances by adding thorium nitrate to a soln. of uranium nitrate in nitric acid, and precipitating with oxalic acid. The filtrate is then evaporated to dryness, and the oxalate decomposed by calcination. The resulting oxide is dissolved in nitric acid, mixed with lead and bismuth nitrate and treated with hydrogen sulphide. The filtrate is then purified by adding a barium salt and precipitating the barium as sulphate. The thorium oxalate precipitation removes radiothorium, ionium, actinium, radio-actinium, and uranium-X; the lead and bismuth sulphide removes the radio-lead and polonium; and the barium sulphate precipitation removes radium, mesothorium, thorium-X, actinium-X, and uranium-X. The process has been discussed by F. Soddy and T. D. Mackenzie, G. N. Antonoff, and S. Meyer and F. Paneth.

Uranium freed from uranium-X emits only α -particles. H. Geiger and E. Rutherford found that each gram of uranium emitted 2.37×10^4 α -particles per second,

while a gram of a mineral in radioactive equilibrium emitted 9.6×10^4 particles per second. They therefore inferred that the decay of the uranium atom is attended with the emission of two α -particles. H. N. McCoy and W. H. Ross, and B. B. Boltwood also concluded that two α -particles are emitted by uranium for one by radium or ionium. E. Marsden and T. Barratt found that it is very unlikely that the uranium atom emits two α -particles simultaneously, because no sign of doubles was observed by the scintillations method; rather was it inferred that the uranium breaks into two distinct substances in equilibrium each one of which breaks up with the emission of one α -particle. Experiments were made by A. Foch, and F. Friedmann; while H. Geiger and J. M. Nuttall showed that two groups of α -rays are emitted from uranium at 15° , one, of range 2.5 cms. and velocity 1.37×10^9 cms. per sec., is emitted by say **uranium-I**—at. wt., 238.5; and the other of range 2.9 cms. and velocity 1.44×10^9 cms. per sec., is emitted by **uranium-II**—at. wt., 234.5. Hence, **uranium freed from uranium-X is a complex containing two components which emit α -rays.** No success has attended the efforts to separate these components by chemical treatment. H. Geiger and F. Rutherford, S. Meyer, H. N. McCoy, and M. S. Curie have deduced that the half-value period of uranium-I is 4.8×10^9 yrs.; the average life period is 7.2×10^9 yrs.; and the radioactive constant $\lambda = 1.4 \times 10^{-10}$ yrs. or 4.4×10^{-18} secs.; while for uranium-II, the half-life period is approximately 2×10^6 yrs.; the average-life period, 3×10^6 yrs.; and the radioactive constant $\lambda = 3 \times 10^{-7}$ yrs. or 10^{14} secs. Uranium-II is the parent of ionium, and is descended from uranium- X_2 .

Uranium-X has an at. wt. 230.5; it emits β -rays; and, as shown by A. S. Eve, and F. Soddy, it also emits feeble γ -rays which have a penetrating power not much less than the γ -rays of radium. The absorption coeff. of the γ -rays for lead is 0.725; for glass, 0.122; for magnesite, 0.0917; for sulphur, 0.0921; and for paraffin wax, 0.0433. H. Richardson found for aluminium 0.70 cm.⁻¹, and 0.140 cm.⁻¹. H. W. Schmidt found that the β -rays are fairly penetrating and have an absorption coeff. 15 cms.⁻¹ for aluminium; it also emits some soft β -rays with an aluminium absorption coeff. of 510 cms.⁻¹. The ionization produced by the soft β -rays was at first ascribed to the emission of some α -rays by uranium-X, but M. Levin showed that this interpretation was wrong. L. Meitner studied the β -rays of uranium-X and showed that their velocity is 95 per cent. of that of light. Uranium-X has not been volatilized. Uranium-X loses its activity in the course of a few months; the loss follows the exponential law. This has been investigated by E. Rutherford and F. Soddy, F. Soddy and A. S. Russell, S. Meyer and E. von Schweidler, V. F. Hess, and G. N. Antonoff, who find that the half-life period is nearly 24.6 days; the average-life period, 35.5 days; and the radioactive constant, $\gamma = 0.0282$ day.

The two sets of β -rays—hard and soft—expelled by uranium-X were shown by K. Fajans and O. H. Göhring to be produced by two consecutive changes, and not by a single change. The two products cannot be separated by recoil, but they can be resolved by chemical and electrochemical methods. F. Soddy and J. A. Cranston found that when a preparation of uranium-X is heated in a current of air and carbon tetrachloride vapour uranium- X_2 is readily volatilized from uranium- X_1 . Both components emit β -rays and γ -rays—the velocity of the β -rays of the one, called **uranium- X_1** , is 1.44×10^{10} to 1.77×10^{10} cms. per sec., and the velocity of the β -rays of the other, called **uranium- X_2** , is 2.46×10^{10} to 2.88×10^{10} cms. per sec. The half-life period of uranium- X_2 is 23.5 days; the average-life period, 33.9 days; and the radioactive constant, $\gamma = 0.0295$ day or 3.41×10^{-7} secs. The half-life period of uranium- X_1 is 1.17 mins.; the average-life period 1.69 mins.; and the radioactive constant, $\lambda = 0.59$ min., or 9.9×10^{-4} secs. These results were confirmed by O. Hahn and L. Meitner, G. N. Antonoff, and by A. Fleck. The absorption coeff. of the hard β -rays from uranium- X_2 is 15 cms.⁻¹ of aluminium; and that of the soft β -rays from uranium- X_1 is 500 cms.⁻¹ of aluminium. H. Richardson attributed the harder γ -rays, with an absorption coeff. of 0.14 cm.⁻¹ of aluminium,

to uranium- X_2 ; and the softer γ -rays, with an absorption coeff. of 24 and 0.70 cms.⁻¹ of aluminium, to uranium- X_1 . G. von Hevesy gave 0.40 sq. cm. per day for the diffusion constant of uranium- X_2 , and said that it corresponded with a quadrivalent element. Uranium- X_2 is a nobler element than uranium- X_1 , i.e. the former deposits on metals more readily than the latter. The closest chemical relation of uranium- X_2 is tantalum, while uranium- X_2 is isotopic with thorium. Uranium- X_2 occupies the vacant place in the periodic table corresponding with *ekatantalum*; it therefore constitutes a distinct chemical type, and its discoverers propose to call it **brevium**, symbol Bv, in reference to its short life. G. von Hevesy, and A. S. Russell interpret the sequence of the decay products so far considered as uranium-I \rightarrow uranium- $X_1 \rightarrow$ uranium- $X_2 \rightarrow$ uranium-II \rightarrow . . . The parent of uranium- X_1 is therefore uranium-I, and that of uranium- X_2 , is uranium- X_1 ; the decay of uranium- X_1 furnishes uranium- X_2 ; and the decay of uranium- X_2 furnishes uranium-II.

The separation of uranium- X_1 from uranium- X_2 was discussed by O. H. Göhring and K. Fajans. Uranium- X_2 is so short-lived that not more than a couple of minutes should elapse between its first precipitation and its exposure to the electroscope. The first method rests on the electronegative character of uranium- X_2 . A feebly acid soln. of uranium-X containing some iron salt was poured into a clean lead capsule, stirred for a minute, and the soln. poured off. The capsule was rapidly washed with alcohol and ether. The deposit of uranium- X_2 can then be tested with an electroscope. A second method rests on the analogy between uranium- X_2 and tantalum, and uranium- X_1 and thorium. If a soln. of tantaliferous uranium- X_2 be tested with a reagent which precipitates tantalum, but not thorium, the tantalum will retain the uranium- X_2 while the uranium- X_1 will remain in soln. O. H. Göhring and K. Fajans precipitated tantalum as hydrated tantic acid from neutral or feebly acid soln. containing potassium hexatantalate. The mixture was filtered, washed by suction, and dried over a hot porous tile. The precipitate retains less than 0.2 per cent. of uranium- X_1 . O. Hahn and L. Meitner proceed as follows:

The mother liquid remaining after the crystallization of uranyl nitrate three times was poured into an excess of a soln. of ammonium carbonate. The uranium-X was dissolved in acid, and filtered. A few milligrams of tantic acid was boiled in water and poured over the uranium-X on the filter. The product was simply dried, or washed and dried. The product was then tested with the electroscope. If a feebly acid soln. be used, a relatively large proportion of uranium- X_1 is retained; while with conc. acid less uranium- X_1 is obtained on account of its solubility in the acid.

If a soln. containing uranium- X_2 , an iron salt, and potassium fluorotantalate be treated with a sat. soln. of potassium sulphate, a flocculent precipitate containing the uranium- X_2 is obtained. If silver nitrate be added to a dil. acetic acid soln. of uranium-X containing iron or thorium, and heated, the precipitated silver retains the uranium- X_2 . If hydrofluoric acid or ammonium fluoride be added to a soln. of uranium-X containing some thorium, the uranium- X_1 will be precipitated with the thorium fluoride, while the uranium- X_2 remains in soln.

S. Meyer and E. von Schweidler, H. Becquerel, and F. Soddy obtained evidence of the association of a short-lived product with uranium-X. G. N. Antonoff found that the decay curve of uranium-X depended on whether it had been separated by precipitating barium sulphate in the uranium salt soln., or by adding a ferric salt and boiling. The decay curve of the former, with either the hard or soft β -rays, was exponential for a period of 24 days, while that of the latter, with the soft β -rays, was faster than normal for the first few days; while if the soft β -rays were screened off, the decay curve was normal. It was therefore inferred that the precipitated ferric hydroxide absorbs a short-lived product, called **uranium-Y**, which is not present in the precipitated barium sulphate. Uranium-Y has been also studied by A. Fleck, A. Piccard and E. Stahel, F. Soddy, O. Hahn and L. Meitner, and E. Rona. The at. wt. is given as 230.5. It was inferred from the decay curve that its half-life period is 25.5 hrs.; its average-life period is 36.8 hrs.; and its radioactive constant $\lambda = 0.46$ day, 2.72×10^{-2} hrs., or 7.55×10^{-6} secs. It emits soft β -rays, for which the

absorption coeff. is 300 cms.⁻¹, and some for which the absorption coeff. is 2500 cms.⁻¹. There is a little evidence of the emission of a very small proportion of α -rays. Uranium-Y is isotopic with uranium-X₁, and is thought by some to be progenitor of the actinium series of radioactive elements. The increase in the activity of uranium freed from uranium-X showed that uranium-Y could not be parent of uranium-X; and the fact that the amount of uranium-Y was independent of the age of the uranium preparation showed that it was not produced by uranium-X. Hence, it is inferred that uranium-Y is a side branch product concurrently formed, in exceedingly minute proportion, with uranium-X, or ionium, Io. The descent is either

J. Danne reported yet another product in uranium-X which he called *radio-uranium*, but the report has not been verified, and it is thought to have arisen from observations on imperfectly purified uranium which contains many radioactive substances. A. Piccard and E. Stahel reported a substance *uranium-V* to be the source of the soft radiations emitted by uranium-X, but O. Hahn showed that the effect is possibly due to the existence of uranium-V.

A genetic connection between uranium and radium is so strongly indicated by the constancy of the U : Ra ratio in minerals, that a search was made for an immediate parent of radium. E. Rutherford and F. Soddy³ originally suggested that uranium is the primary source of radium, but the last-named found that the rate of production of radium in soln. of uranium nitrate, freed from uranium-X, was a thousand times smaller than would obtain if the uranium passed directly into radium. B. B. Boltwood likewise detected no growth of radium, over a period of 390 days, in a soln. containing 100 grms. of purified uranium nitrate. These results showed that uranium does not change directly into radium, but that an unknown product of slow transformation occurs as an intermediate product in the passage of uranium to radium. B. B. Boltwood at first concluded that actinium was the missing intermediate product because the radium content of a sample derived from carnotite increased by 8.5×10^{-1} grms. in 193 days. E. Rutherford, however, found that while some samples of actinium behaved like B. B. Boltwood's specimen, other samples did not grow radium to an appreciable extent. It was therefore concluded that the parent of radium was not actinium itself, but rather an unrecognized radioactive component present in actinium. B. B. Boltwood named this product **ionium**, Io. He found that the ionium followed the actinium in the separation from the uranium minerals. Actinium and ionium can be separated. Nearly all uranium minerals contain some thorium, but neither B. B. Boltwood nor B. Keetman were able to separate ionium from thorium. The two elements cannot be separated by the fractional sublimation of the acetylacetones, and it is doubtful if ionium has been obtained free from thorium. The only way to get ionium free from that element is to find a mineral containing no thorium. F. Soddy added:

Its chemistry can be fully and accurately described in a single sentence. It resembles thorium in its whole nature, as far as it is known, with absolute completeness, so that not only is no separation of the two elements possible by any known method, but no concentration of the one constituent with reference to the other has been accomplished. Such an alteration of concentration could be readily detected, if it occurred, even with the infinitesimal amounts of ionium used, because of the intense α -activity of the latter. Thorium and ionium form a pair of non-separable elements. Radio-thorium, certainly, and, according to some authorities, uranium-X, are also non-separable from thorium. This apparently complete chemical identity of different elements of, in some cases, different at. wt., is one of the most important results of the study of radioactivity, and many other examples will occur. It must be remembered that the chemistry of thorium has been closely and exhaustively studied on account of its resemblance to and association with many other rare earths of no technical value, and in consequence a large number of characteristic and effective methods for the purification of thorium from all other elements are known.

In working the uranium ores for radium by the processes of M. S. Curie, L. Haitinger and C. Ulrich, etc., the ionium will be found with the rare earths. The usual

method of separating thorium from minerals is to add a thorium salt, except with minerals definitely thoriferous, and then proceed to precipitate the thorium by the standard methods—*e.g.* with sodium thiosulphate, ammonium carbonate, oxalic acid, or hydrofluoric acid. The ionium follows the thorium. The radioactivity of thorium is much smaller than that of ionium. Cerium salts have been used in place of thorium, the ionium follows the cerium; and the cerium can be separated from the ionium by the standard methods for separating cerium from thorium. B. Keetman used aluminium salts in place of thorium salts. C. A. von Welsbach removed lead, etc., by adding sulphuric acid to a nitric acid soln. of pitchblende; he then precipitated the fluorides, and fractionally precipitated the soln. of the fluorides in boiling sulphuric acid by means of zinc hydroxide slurry. The first precipitate contained all the thorium and ionium. B. Keetman said: If not too great an excess of zinc hydroxide be employed, the last traces of ionium can be separated from the rare earths; but a repetition of the process is necessary or the product will be contaminated with some cerium and didymium. The separation of zinc is effected by treating the acid soln. with ammonia, or soda-lye, or hydrofluoric acid. B. Keetman also found that in the presence of phosphoric acid, soln. of the rare earths are quantitatively precipitated as fluorides, lead and calcium fluorides are also precipitated, while uranium, iron, etc., remain in soln. He recommended the following process for separating ionium from uranium minerals:

The uranium ore was dissolved in warm dil. nitric acid, and the soln. evaporated to dryness to make the silica insoluble. The mass was digested with dil. nitric acid, and the filtrate evaporated with sulphuric acid to convert the nitrates to sulphates. When the soln. is diluted with water, barium, radium, and lead sulphates are precipitated. The filtrate was then boiled with hydrofluoric acid in a platinum dish. The precipitated fluorides were collected on a filter, again decomposed by heating with sulphuric acid, and then dissolved in water. Oxalic acid was added, and the precipitate digested with a hot conc. soln. of ammonium oxalate, and diluted with water. The yttria earth-oxalates are filtered off, the soln. containing thorium and ionium. The oxalates are precipitated by adding hydrochloric acid. B. Keetman obtained 0.1 gm. of very radioactive thorium oxalate from 200 grms. of African pitchblende.

H. M. Plum has described the separation of ionium from carnotite. E. Rona estimated the ionium content of various radium residues. B. B. Boltwood found that the amount of ionium in a number of minerals was proportional to the amount of uranium; and rate of production of radium was proportional to the amount of ionium. Ionium and radium are separated by adding barium chloride to the sulphuric soln., radium sulphate precipitates with the barium sulphate, and uranium remains in the filtrate. In course of time, however, radium re-forms in the ionium soln. Radium was generated from ionium at a constant rate over the period of measurement—500 days. The slow growth of radium in soln. of uranium salts observed by F. Soddy was due to the small quantity of ionium initially present; F. Soddy and T. D. Mackenzie found no detectable growth of radium in uranium soln. from which the ionium had been previously separated, but radium did grow in soln. of ordinary uranyl nitrate which contain ionium. Hence, too, as O. Hahn has shown, all thorium preparations containing ionium will generate radium—in minute quantities. Uranium-II is thought to be the parent of ionium, and ionium the parent of radium.

The at. wt. of ionium is estimated to be about 230. F. Exner and E. Haschek, A. S. Russell and R. Rossi, and O. Hönigschmid examined the spectrum of thorium-ionium preparations estimated to contain 10 per cent. of ionium; the spectral lines of thorium were obtained, but not a single line that could be attributed to ionium. The radioactivity of ionium resembles that of polonium. According to B. B. Boltwood, L. P. Wheeler and T. S. Taylor, S. Meyer and co-workers, B. Keetman, and E. Rutherford, it emits α -rays of range of about 3 cms. at 15° and of initial velocity 1.46×10^9 cms. per sec. B. B. Boltwood observed a transient β -ray activity which decayed in 22 days, indicating that it was produced by uranium-X which had been separated with the ionium. J. Chadwick and A. S. Russell found that ionium

purified from the radioactive bodies which emit β - and γ -rays, emitted a small but easily detectable amount of γ -radiation. This radiation is shown to be excited by the α -rays, either in the ionium itself or in the thorium with which it is mixed. It is a mixture of three types of radiation differing widely in penetrating power. The absorption coeff. divided by the sp. gr. of aluminium are respectively 400, 8.4, and 0.15 cms.⁻¹. Estimates have been made of the life of ionium by F. Soddy, B. B. Boltwood, and H. Geiger and J. M. Nuttall; the best representative values are 2×10^5 yrs. for the half-life period, and 3.5×10^5 yrs. for the average-life period. According to F. Soddy:

Ionium possesses the great advantage over polonium for many purposes, in that its radioactivity is constant and does not sensibly decay. It will no doubt find large application where a steady, powerful source of α -radiation is required, as in compensation methods of radioactive measurement and for α -ray standards more active than those of uranium. The proportion changing into radium, even in a lifetime, is so small that it may in most cases be neglected. It is only by refined emanation tests that it can be detected.

Table V gives a summary of the radioactive properties of the uranium radium family. A new radioactive substance, designated *uranium-Z* until its parentage is definitely elucidated, and having the chemical properties of protactinium, was shown by O. Hahn to be present in ordinary uranium salts. It emits β -radiations, and has a half-life period of 6.7 hrs. Under the prescribed conditions the intensity of radiation of the new substance is only about 0.25 per cent. of that of uranium-X, that is, a mixture of uranium-X₁ and -X₂, obtained from the same quantity of uranium. The parent substance can be only uranium-X₁, or a new isotope of similar life-period.

TABLE V.—SUMMARY OF RADIOACTIVE CONSTANTS OF THE URANIUM-RADIUM SERIES.

	At. wt.	Half-life Period.	Radioactive constant, λ .	Rays.	Velocity α -rays cm./sec.	Velocity β -rays (Light unity).
Uranium-I . . .	238.2	5×10^9 yrs.	4.3×10^{-18}	α	1.36×10^9	—
Uranium-X ₁ . . .	234.2	23.5 d.	3.3×10^{-7}	β, γ	—	wide range
Uranium-X ₂ . . .	234.2	1.7 min.	0.01	β, γ	—	0.52, 0.65
Uranium-II . . .	234.2	2×10^6 yrs.	1.1×10^{-14}	α	1.44×10^9	—
Uranium-Y . . .	230.2	25.5 hrs.	7.5×10^{-6}	β	—	—
Ionium . . .	230.2	10^5 yrs.	2.2×10^{-13}	α	1.47×10^9	—
Radium . . .	226	1730 yrs.	1.26×10^{-11}	α, β	1.50×10^9	—
Ra Emanation . . .	222	3.85 d.	2.08×10^{-6}	α	1.62×10^9	—
Radium-A . . .	218	3.0 mins.	3.85×10^{-3}	α	1.70×10^9	—
Radium-B . . .	214	26.8 mins.	4.33×10^{-4}	β, γ	—	0.36 to 0.74
Radium-C ₁ . . .	214	19.5 mins.	5.93×10^{-4}	α, β, γ	1.92×10^9	0.80 to 0.98
Radium-C ₂ . . .	210?	1.4 mins.	8.3×10^{-3}	β	—	—
Radium-C' . . .	210	10^{-6} sec.?	7×10^5	α	—	—
Radium-D . . .	210	16.5 yrs.	1.39×10^{-9}	β	—	0.33, 0.39
Radium-E . . .	210	5.0 d.	1.66×10^{-6}	β, γ	—	wide range
Polonium (RaF) . . .	210	136 d.	5.90×10^{-8}	α	1.58×10^9	—

§ 11. The Descendants of Uranium and Radium

The habit of suspending judgment until the conclusion has been fully tested by varying the circumstances of the experiment, and by repeated accurate measurement, is a valuable habit to acquire.—G. F. FITZGERALD.

It is assumed that the element uranium, after a long series of transformations, passes into a form of matter which has no radioactivity or a radioactivity too feeble to be detected by available methods. The successive stages are summarized in Table VI, where the at. wt., the nature of the radiations, and the half-life period are indicated. The side branches involving uranium-Y and radium-C₂ have been

omitted. The radioactivity of aged uranium is therefore a complex quality because of the presence of the decay products. B. B. Boltwood has estimated that if the radioactivity of uranium as oxide be unity, the relative activities of the various products in the mineral uraninite are :

U	Ra	Nt	Ra _A	Ra _B	Ra _C	Po or Ra _F	Ac products
0.34	0.45	0.62	0.54	0.04	0.91	0.46	0.28

so that the total activity of the mineral is 4.64 times that of the contained uranium ; and a gram of radium freed from all products has the activity of 1,300,000 grms. of uranium. The subject has also been studied by H. N. McCoy and W. H. Ross. L. Meitner discussed the mechanism of the radioactive disintegration of the elements.

TABLE VI.—GENEALOGICAL TREE OF THE URANIUM-RADIUM FAMILY.

α-rays	(5×10^{19} years)	Uranium-I (238.18)
↓		↓
β- and γ-rays	(23.5 days)	Uranium-X ₁ (234.18)
↓		↓
β- and γ-rays	(1.7 mins.)	Uranium-X ₂ (234.18)
↓		↓
	(2×10^6 years)	Uranium-II (234.18)
↓		↓
α-rays	(1×10^5 years)	Ionium (230.18)
↓		↓
α- and β-rays	(1730-375 years)	Radium (226)
↓		↓
α-rays	(3.85 days)	Emanation (222)
↓		↓
α-rays	(3.0 mins.)	Radium-A (218)
↓		↓
β- and γ-rays	(26.8 mins.)	Radium-B (214)
↓		↓
β- and γ-rays	(19.5 mins.)	Radium-C ₁ (214)
↓		↓
β-rays	(16.5 years)	Radium-D (210)
↓		↓
β- and γ-rays	(5.0 years)	Radium-E (210)
↓		↓
α-rays	(136 days)	Radium-F (210)
↓		↓
α-rays		Radium-G (206)

The alternative name for uranium-X₂ is *brevium* ; for radium emanation, *niton* ; and for radium-F, *polonium*. Radium emanation is preferred by physicists, chemists often use *niton*. M. C. Neuburger has discussed the nomenclature of radiochemical transformations. There are facts which support B. B. Boltwood's hypothesis¹ that radium-G is lead. The evidence that polonium passes spontaneously into lead is at present purely circumstantial. W. R. Gray reported that he found lead in some capillary tubes in which a minute quantity of radium emanation had been stored for four years. There are three possible sources of the lead : (a) the glass of the tubes contained 0.03 per cent. of lead ; (b) the mercury used to seal the tubes contained a trace of lead ; (c) the disintegration of the emanation, *à la* the emanation hypothesis. The glass of the tube was undoubtedly attacked by the emanation as shown by the discoloration, although no measurable amount of lead was obtained by digesting the powdered glass with water for some time. The alleged generation of lead is thought to be due to the confusing of isotopic radium-D with lead.

K. Fajans and H. Towara suggested that a *radium-H* is formed from radium-G by the emission of β -rays, and that radium-H gives off α -rays producing an isotope of thallium. This would account for the presence of thallium and bismuth in pitchblende. The range of the α -particles was about 3 cms., the half-life period is between 10^6 and 10^8 yrs. L. Meitner, and O. Hönigschmid have discussed this subject.

It has been argued that if the end-products of the radioactive transformations are stable and non-volatile, these products must be accumulating in the radioactive minerals. The amount of the end-product in the unaltered mineral would be expected to depend on the amount of the parent element originally present, and on the age of the mineral. B. B. Boltwood examined a number of old unaltered minerals, and was led to suggest that lead is the end-product of the uranium-radium series, because the ratio Pb : U is nearly constant for unaltered minerals from the same locality, and presumably the same geological age, but the ratio varies with minerals from different localities. For example, five uraninites from Glastonbury (Conn.) had a ratio 0.041; five from Branchville had the ratio 0.053; one from Texas, 0.170; thorianite from Ceylon had a ratio 0.20; a group of minerals from Norway had the ratio 0.125, and another group, 0.155. A. Holmes also extended the observations and found the ratio to be unaffected by the presence of thorium, showing that this element is not genetically related with lead. The decay of uranium is attended by the expulsion of eight α -particles, *i.e.* eight atoms of helium; it follows that the amount of the assumed lead—at. wt. 238.18, minus $8 \times 3.994 = 206.3$ —formed per gram of uranium per year is 1.25×10^{-10} grms. Hence, assuming that the rate of production of lead has remained constant, the maximum age of a mineral will be $\text{Pb}/1.25 \times 10^{-10} \text{U}$, or $8 \times 10^9 \text{Pb/U yrs.}$ A. Holmes gives the results indicated in Table VII. The estimate represents maximum values because of the

TABLE VII.—RATIO OF LEAD TO URANIUM IN MINERALS.

Geological Period of Mineral.	$\frac{\text{Pb}}{\text{U}}$	Age in millions of years.
Carboniferous	0.041	340
Devonian	0.045	370
Pre-Carboniferous	0.050	410
Silurian or Ordovician	0.053	430
Pre-Cambrian—Sweden	0.125-0.155	1025-1270
United States	0.160-0.175	1310-1435
Ceylon	0.200	1640

possibility of some of the lead having been deposited with the minerals first, and estimations based on the occluded helium represent minimum values because a part of the gas must have escaped.

According to O. Hönigschmid, the at. wt. of uranium is not less than 238.08, and not greater than 238.18. If lead is formed by the loss of eight atoms of helium, at. wt. 3.994, the computed value for the at. wt. is 206.23; the at. wt. of ordinary lead is 207.20. Similarly, if lead is formed from radium, at. wt. 226, by the loss of five α -particles, the at. wt. should be 206.03. Lead derived from an analogous series of radioactive transformations is computed by K. Fajans and F. Soddy to have an at. wt. 208.4. The discrepancy attracted attention to the possibility that lead from uranium earths may not have the same at. wt. as ordinary lead. F. Soddy and H. Hyman tried if the at. wt. of lead extracted from the mineral thorite and ordinary lead showed any difference. They reported that the former gave the larger result, though no special precautions were taken to eliminate silver. The at. wt. of thorite lead being 208.3-208.5; M. Curie similarly found that lead derived from monazite had an at. wt. 207.08; that from pitchblende, 206.5; that from galena, 207.01. T. W. Richards and M. E. Lemberg found lead derived from uraninite of Carolina had an at. wt. 206.40; that from pitchblende of Joachimsthal, 206.37; that from carnotite of Colorado, 206.59; that from thorianite of Ceylon,

206.82; that from pitchblende of Cornwall, 206.86; and that from commercial lead, 207.15. T. W. Richards and C. Wadsworth extended these observations to lead obtained from various radioactive minerals. Confirmatory observations were made by T. W. Richards and J. Sameshima, T. W. Richards and W. C. Schumb, O. Hönigschmid and S. Horovitz, A. L. Davis, M. Muguet, and K. Fajans. Hence, it has been inferred that "there are several varieties of lead of different at. wt. determined by the element from which they are derived." In general, **lead derived from radioactive minerals has a different atomic weight from ordinary galenic lead.** T. W. Richards added:

The inference seems to be that radioactive lead contains an admixture of some substance different from ordinary lead, and very difficult to separate from it by chemical means. This substance cannot be identified in the ultra-violet spectrum of the material, either because it has the same spectrum as lead, or because it has no spectrum in that part of the field, or because its spectrum is masked or absorbed by that of lead.

The spectra of the different specimens of lead have been examined by T. W. Richards and co-workers, F. Soddy and H. Hyman, F. Haschek, and O. Hönigschmid and S. Horovitz, from which it is concluded that the spectra of lead derived from radium, and from *plumbum commune*, both in the visible and ultra-violet regions, with λ between 2380 and 4470, are identical. T. W. Richards and C. Wadsworth showed that *plumbum commune*, at. wt. 207.2, had a sp. gr. 11.337 at 19.94, whereas a sample of Australian radioactive lead, at. wt. 206.3, had a sp. gr. 11.288. The two samples thus had virtually the same at. vol. 18.276 and 18.277.

The expulsion of an α -particle from an atom lowers the at. wt. of the original atom by 3.994, say 4, the at. wt. of helium. Thus, the at. wt. of radium is 226, that of niton 224, and that of helium 4. It follows, therefore, that radium \rightarrow niton + helium. The assumption is employed in estimating the at. wt. of the other radioactive substances. The emission of β -rays, i.e. electrons, is supposed to produce no measurable change in the at. wt., while the emission of α -rays (charged helium atoms) at each stage of the disintegration is supposed to reduce the at. wt. by 4. F. Soddy pointed out that the expulsion of an α -particle by a radioactive element causes the residual product to shift its position two places in the periodic table in the direction of diminishing mass, so that the residual product is not in the next family, but in the next but one. This reduces the valency of the element by 2. For example, sexivalent uranium loses an α -particle to form uranium-X, isotopic with thorium, and therefore quadrivalent; quadrivalent ionium loses an α -particle, forming bivalent radium; and the latter loses an α -particle to form nullvalent niton. A. S. Russell² expressed the **displacement rule**: *whenever an α -particle is expelled by a radioactive element the group in the periodic table to which the resultant product belongs, is either two units greater or two units less than that to which the parent belongs.* Similarly, *when an element gives off a β -particle with or without the accompaniment of γ -rays, the resultant product shifts its position so that it is one unit greater or one unit less than that to which the parent belongs.* Hence, two changes attended by the emission of β -particles, and one by an α -particle, could bring the product back to its original position in the periodic table. When a body like radium-C expels both α - and β -rays, the group to which the resultant product belongs may differ from that of the parent by $2 \pm 1 = 1$ or 3. These rules are illustrated by the arrangement, Fig. 15, showing the position of the decay-products of the uranium-radium series in the periodic table. The subject of isotopism has also been discussed by K. Fajans, A. Fleck, F. Paneth, G. von Hevesy, F. Kirchhof, A. van den Broek, S. Meyer, O. Hahn and L. Meitner, I. W. D. Hackh, F. J. Corrigan, M. L. Neuburger, E. Hendrick, R. Brunetti, W. D. Harkins, etc.

F. Soddy postulated that when any number of elements occupy one place in the periodic table, these elements cannot be separated from one another by any known chemical process. Thus, when mesothorium-I gives off two β -particles and

one α -particle to form thorium-X, it is claimed that the two substances cannot be separated from one another in spite of the difference in their at. wts.; and they are probably spectroscopically indistinguishable. F. Soddy called the non-separable elements **isotopic elements**, or **isotopes**—*ἴσος*, the same; *τόπος*, a place—because they occupied the same place in the periodic table. K. Fajans suggested the term *pleiadic elements* or *pleiades*—after the small group of stars in the constellation Taurus—e.g. ionium, thorium, and radio-thorium are isotopic; and mesothorium is isotopic with radium. F. W. Aston uses *isobares* as a general name for atoms having

FIG. 15.—Arrangement of the Uranium-Radium Decay Products in the Periodic Table.

the same mass but different chemical properties. F. Sekera has discussed the nomenclature of isotopism. A number of isotopes of non-radioactive elements have been detected by positive ray analysis (*q.v.*). The principle of isotopy is not in conformity with J. Dalton's dogma:

The ultimate particles of all homogeneous bodies are perfectly alike in weight, figure, etc. In other words, every particle of water is like every other particle of water, and every particle of hydrogen is like every other particle of hydrogen.

The alleged inseparability of the isotopes may be questioned as a reflection on the skill of succeeding chemists. H. S. Shelton maintains that if the atoms of an element be regarded as entities varying about a mean, so must also the properties referred to the atom. In 1888, W. Crookes postulated atoms of variable at. wt., but also assumed a concomitant variation of properties.

The different forms of lead discovered by F. Soddy connected with radioactivity are also said to be isotopic, for they are said to be inseparable, having the same at. vol. and the same chemical and physical properties; but F. A. Lindemann has shown that two elements of different at. wt. must differ either in their chemical or physical properties. The argument is based on the laws of thermo-dynamics, and was extended in conjunction with F. W. Aston. The subject was discussed by K. Fajans and co-workers, R. A. Mulliken and W. D. Harkins, etc. If the at. vols. are the same, the elastic constant, vap. press., etc., should differ, and it was predicted that the lead from thorite will probably have a m.p. 1.54° higher than ordinary lead. K. Fajans concludes that at absolute zero the at. vols. of isotopes should be the same, and they should differ progressively as the temp. rises; at ordinary temp. with the lead isotopes, the difference should be less than 0.0001 part. J. Joly and J. H. J. Poole attempted to separate lead isotopes by centrifuging the molten metal, and obtained a negative result. The sp. hts. in the case

of lead isotopes should differ by about 0.75 per cent. S. Chapman, O. Stern and M. Volmer, and E. Kohlweiler discussed fractional diffusion; and R. S. Mulliken and W. D. Harkins showed that isotopes should exhibit differences in their rates of diffusion through porous walls, and in their rates of evaporation into a vacuum. J. N. Bronsted and G. von Hevesy failed to separate mercury isotopes by fractional evaporation. T. W. Richards and N. F. Hall found the β -ray activity of different fractions of isotopic lead were the same. A. Haas discussed the spectroscopy of isotopes; W. D. Harkins and L. Aronberg showed that there must be spectral differences between the spectra and between other properties of isotopes; M. Siegbahn and W. Stenström found the L- and M-series of X-ray spectra of lead isotopes are the same; C. D. and D. Cooksey observed no difference in the high-frequency spectra of lead isotopes. F. W. Loomis showed differences probably occur in the infra-red spectra of the isotopes of chlorine; and T. R. Merton and H. Hartley suggested that by exposing chlorine to light and then to hydrogen, the heavier isotope will react the faster. T. W. Richards and W. C. Schumb found the refractive indices of the crystals of isotopic lead nitrate were the same. T. W. Richards and N. F. Hall found the molar solubilities of the isotopes of lead to be virtually the same because a thousand fractional crystallizations produced no separation. T. W. Richards and W. C. Schumb found no difference in the molar solubilities of the nitrates of common lead and lead from uranium minerals. If the molar solubilities are the same, then, since the mol. wts. are different, the solubilities in grams per litre, and the sp. gr. of sat. soln. ought to show small differences; and K. Fajans and co-workers found the sp. gr. of sat. soln. have the same ratio to the mean sp. gr. as the difference in the at. wt. to the mean at. wt. H. Lachs and co-workers failed to separate uranium-I and -II by fractional diffusion. G. von Hevesy and F. Paneth have established the electrochemical identity, and Z. Klemensiewicz, the electrode potential identity of isotopic elements—within the limits of their methods of measurement. E. Schrödinger discussed the reversible mixing of two gases of different mol. wt., and chemically inert to one another. R. S. Mulliken discussed the separation of isotopes by thermal and press. diffusion; T. Iredale, the possibility of isotopic elements furnishing asymmetric atoms in enantiomorphic compounds. The difference in the series spectra of isotopes was discussed by P. Ehrenfest, N. Bohr, and J. W. Nicholson.

C. T. Kingzett³ maintained that *isotopism* is another name for *allotropism*, and that isotopes are "atomically or molecularly modified form of one and the same substance, although possibly possessed of distinctive at. numbers or mol. wts." A. Fleck held that the two phenomena are quite distinct, that isotopism refers to a difference in the at. wts. of individual atoms, and that multiples of atoms are not involved.

§ 12. Actinium and its Putative Parent

In 1899, A. Debierne,¹ while working up uranium residues for M. S. Curie in her quest for the cause of the radioactivity of pitchblende, found that the precipitate obtained by ammonia had a very marked radioactivity. He called the element *actinium*, but said it could not be separated from thorium. Soon afterwards, F. Giesel obtained a radioactive substance from pitchblende; it separated along with the rare earths and was ultimately obtained admixed with lanthanum. He called it *emanium*, and concluded it was not identical with A. Debierne's actinium because emanium was not separated with thorium. Later, A. Debierne found that his preparation emitted an emanation similar to that of F. Giesel's preparation, and it was found that the observation about thorium was wrong. After some controversy, it was agreed that only one radioactive substance was involved, and it was called **actinium**, Ac. E. Rutherford and B. B. Boltwood showed that the original preparations also contained ionium. O. Hahn and O. Sackur established the identity of the emanations of actinium and emanium; and W. Marckwald's claim that the two are not the same substance, but are genetically related with one another, was shown by O. Hahn to be due to the presence of another radioactive substance—radioactinium—in one of the preparations.

Actinium is always found in uranium minerals, but not in the purely thorium

minerals. B. B. Boltwood found that the ratio $U : Ac$ is fairly constant. Actinium is usually extracted from the residues obtained in the treatment of uranium ores—pitchblende and carnotite. A. Debiere and M. S. Curie obtained the hydroxides of actinium with iron and the rare earths by working up the residues from the pitchblende. The acid soln. was treated with hydrogen sulphide to remove the polonium and radio-lead oxidized; and then treated with ammonia. The precipitate contains hydroxides of actinium mixed with those of iron and the rare earths.

The precipitation by ammonia was found by M. Levin, O. Hahn, B. B. Boltwood, and C. A. von Welsbach to be incomplete in the presence of ammonium salts, and these can be removed by evaporating the soln. to dryness, and heating the residue with boiling nitric acid or aqua regia. The excess of acid is removed by evaporation. H. M. Plum found it impossible to separate all the actinium from radiferous and actiniferous barium chloride in one precipitation even in the presence of aluminium chloride. It required three re-solutions and precipitations to separate the radium and actinium. C. A. von Welsbach noted that actinium is readily separated with manganese when that element is precipitated from basic soln. as manganite. Actinium, unlike thorium and ionium, is not precipitated from its nitrate soln. by the addition of hydrogen peroxide.

The hydroxides are treated with dil. hydrofluoric acid, part—zirconium, titanium, etc.—goes into soln., but most of the radioactive constituent remains with the insoluble fluorides of thorium, cerium, didymium, and lanthanum. The fluorides are then converted into sulphates, then to chlorides, and the soln. treated with oxalic acid, or ammonium oxalate. The conc. of free acid in the soln. for the oxalate precipitation should be reduced to a minimum, since actinium oxalate, like lanthanum oxalate, is distinctly soluble in mineral acids. The precipitated oxalates are then ignited and dissolved in nitric acid. Actinium can be conc. to some extent by fractional crystallization of the double salts with magnesium nitrate or manganese nitrate. The actinium collects with the samarium and neodymium as in the process of E. Demarçay; and it can also be conc. to some extent by taking advantage of the fact that when barium is precipitated as sulphate from a soln. containing barium and actinium, the latter is adsorbed by the precipitate. This property was utilized in the separation of actinium from pitchblende and the ore from Olary (South Australia).

F. Giesel separated the rare earth precipitate by the potassium sulphate and oxalate method, and found the radioactive constituent followed the cerium earths. The actinium was retained very tenaciously by the lanthanum, but it is possible to separate some lanthanum from actinium by the magnesium nitrate process. B. Keetman found that in recrystallizing cerium oxalate from nitric or hydrochloric acid, actinium collects in the most soluble fraction. K. A. Hofmann and F. Zerban employed a process somewhat similar to that used by A. Debiere. They state that actinium oxalate is soluble in a warm soln. of ammonium oxalate, but unlike thorium oxalate, it cannot be reprecipitated by the addition of ammonia or acids; the dried sulphate is only sparingly soluble in ice-cold water; the ignited oxide dissolves readily in conc. sulphuric acid; and it is precipitated by sodium thio-sulphate. C. A. von Welsbach found that whereas the contained ionium followed all the reactions of thorium, actinium stands between lanthanum and calcium, but it follows all the reactions of the former. He separated impure actinium from the hydroxide precipitate by what he called the oxalate method and also by the sulphate method.

In the sulphate method, the moist hydroxides were treated with sulphuric acid, and the soln. filtered from the residual basic bismuth sulphate, and the lead and rare earth sulphates. The mother liquid was conc. to remove iron-alum, and treated with oxalic acid. The radioactive actinium in the precipitate followed the reactions of lanthanum. It separated out in several cases as a manganate when the mother liquor from the oxalate precipitations was kept, a reaction which proved of great service, for actinium is, in the presence of ammonium salts, not completely precipitated either by ammonia or ammonium oxalate. From the soln. of the first precipitate of rare earth oxalates, freed from heavy metals, hydroxides were fractionally precipitated in presence of much ammonium nitrate by precipitating a portion with ammonia and stirring it into the main quantity of the

mixture of hydroxides. The most basic part is iron, then come thorium, uranium, scandium, the ytterbium group, the yttrium group, the cerium group, whilst calcium and analogous elements remain in soln. From the rare earths the greater part was removed inactive by precipitation of the sulphates with ammonium sulphate, the radioactive matter keeping with the rare earths in soln., and with those the oxalates of which are soluble in ammonium oxalate. (e.g. thorium).

In the oxalate method the hydroxides were dissolved in hydrochloric acid, the bismuth precipitated as basic chloride by ammonia, and the filtrate precipitated with oxalic acid and then with ammonia, so long as the oxalate precipitate increased. The soln. of the rare earth oxalates, freed from heavy metals, was precipitated by ammonia as just described so as to give the iron, thorium, and uranium in one fraction, which contained all the radioactive matter. The actinium can be obtained with the lanthanum and the ionium with the thorium by various methods.

There are two descendants of actinium, namely, radioactinium and actinium-X, which, according to O. Hahn and M. Rotenbach, can be separated by the following process. A trace of purified thorium nitrate and a little zirconium nitrate are added, and the radioactinium is separated by treatment with sodium thiosulphate since actinium is not precipitated from a boiling soln. in the presence of that salt; while radioactinium is precipitated by ammonia. A little barium nitrate is added to the soln. to retain the actinium-X, and the actinium is then precipitated with ammonia. The precipitate is dissolved in dil. hydrochloric acid, mixed with barium chloride and sodium acetate, and treated with potassium dichromate, actinium-X separates with the barium chromate. Ammonia precipitates actinium from the filtrate; this is redissolved and reprecipitated a number of times. The operations here indicated should be conducted without delay in order to avoid the re-formation of radioactinium.

According to E. Rutherford, "less is known about actinium as a radioactive element than of any other, for it has been found impossible to isolate it from the rare earths with which it is mixed, and to locate its position in the scheme of transformations." It has not been obtained of a sufficient degree of purity to furnish a characteristic spectrum. The absence of any new lines in the spectrum led E. Rutherford to say that it appears probable that actinium, if it could be obtained in the pure state, would show an activity as great if not greater than that of radium. The preparations of actinium are usually mixtures of compounds of the rare earth elements with very minute proportions of actinium compounds. A. Debiere noted the resemblance which actinium bears to the rare earth elements, and, as F. Giesel, and D. Strömholm and T. Svedberg showed, actinium most resembles the trivalent elements of the cerium group, and more particularly lanthanum, with which it forms isomorphous salts.

For its at. wt., *vide infra*, K. A. Hofmann and F. Zerban estimated the equivalent to be 63.32, but this number is probably too small. G. von Hevesy's diffusion experiments make actinium a trivalent element; and it is isotopic with mesothorium-II. He also found that the presence of actinium in uranium can be shown directly by the emission of its short-lived emanation, when a rapid current of air is aspirated through a soln. of the mineral into an electroscope. D. Strömholm and T. Svedberg found that actinium is not volatile at a red heat under ordinary conditions. Actinium is an unstable element, for, like radium, thorium and uranium, it is continuously breaking down at a slow and definite rate to furnish a consecutive series of disintegration products. Actinium is in a state of equilibrium with these products in about three months after the preparation has been made. In that state, α -, β -, and γ -rays are emitted by actinium preparations; but when freed from these products, actinium is either rayless or emits radiations of very feeble intensity. F. Giesel observed that aged preparations of actinium emit an emanation or a gas whose radioactivity decreases to its half-period value in a few seconds. E. Rutherford illustrates the emanating property of aged actinium by the following experiment:

A highly active preparation of actinium enclosed in thin tissue paper is placed on a screen of phosphorescent zinc sulphide. In a dark room a brilliant phosphorescence, marked

by characteristic scintillations, extends for some distance from the active preparation. On directing a slight current of air across the screen, the phosphorescence is displaced in the direction of the air current, and becomes much feebler. A large part of the phosphorescence observed initially was due to the actinium emanation which diffused through thin paper over the surface of the screen. When the air current ceases, the emanation which is constantly supplied by the actinium, rapidly diffuses over the screen and lights it up again brightly.

The β -rays emitted by actinium in equilibrium with its decay products are of low penetrative power; while the γ -rays are feeble both in intensity and in penetrating power. M. S. Curie estimated the average-life period of actinium to be about 30 years; the estimate was based on the 10 per cent. decrease in the β -ray activity which occurs in old actinium preparation in three years. This estimate was confirmed for an actinium preparation studied for seven years by O. Hahn and L. Meitner, as well as for some recently prepared specimens. From the increase in the α -radiation of the parent of actinium, namely, protoactinium, they estimate a half-life period of 20 years (± 10 per cent.), and an average-life period of 28.8 years. Aged actinium preparations give off α -rays which merge into helium, and, as A. Debierne has shown, they slowly decompose aq. soln. with the evolution of hydrogen and oxygen. S. Meyer estimated the half-life period of actinium to be 16.5 years; and the transformation ratio of actinium and radium in the uranium family to be 4 : 96—E. Rutherford gave 8 : 92; G. Kirsch, 4.2 : 95.8; and O. Hahn and L. Meitner, 3 : 97.

B. B. Boltwood² showed that in aged uranium minerals the ratio of the proportion of uranium and actinium is approximately constant. This observation was confirmed by S. Meyer and V. F. Hess, and H. N. McCoy and co-workers. This fact is taken to indicate that actinium is derived from uranium. Since the α -ray activity of actinium is very small in comparison with that of the uranium-radium series of products, in the same mineral, E. Rutherford suggested that some member of the series disintegrates concurrently in two ways, and each of the products continues disintegrating. As a result, there are two series of decay products, one furnishing the actinium and the other the radium series. There has therefore been some speculation as to the precise point at which this branching occurs. It was argued by F. Soddy, from the displacement rule—*vide supra*—that since actinium is a member of the third group of the periodic table, its parent must belong to the fifth group and be a homologue of tantalum if it is formed by an α -ray change; and if formed by a β -ray change, its parent will be a member of the second group isotopic with radium. Radium is the only member of the uranium series in the second group. F. Soddy showed it to be very unlikely that radium is the parent. No actinium was found in a preparation containing 13.2 mgrms. of elemental radium 10 years old. The negative result corresponded with a period of at least 15×10^6 years, whereas the period is shown to be about 30 years. The alternative assumption is that actinium is derived from an element in the fifth group by an α -ray change; and since brevium is short-lived and gives no α -rays, it follows that an unknown isotope must exist in the uranium series. O. Hahn and L. Meitner suggest that the series may branch at uranium- X_1 , and β -rays expelled from each so as to furnish two isotopic products. Uranium-Y gives a β -radiation, and therefore its unknown product must occupy the place of ekatantalum in the periodic table, and be isotopic with uranium- X_2 or brevium. If uranium-Y undergoes an α -ray change, the product must be actinium or an isotope, and it should be present in uranium minerals. This was established by F. Soddy and J. A. Cranston. They found uncertain indications of actinium in four-year-old preparations of uranyl nitrate, but increased amounts in preparations eight years old.

O. Hahn and L. Meitner separated the putative parent of actinium, which they called **protoactinium**, from the siliceous residues remaining after the prolonged and repeated treatment of pitchblende with nitric acid so as to remove radium and other radioactive constituents. A little tantalum salt was added, and it was found that the reactions so closely followed those of tantalum that the two elements were

associated together at the end of the operations as inseparable companions. The process employed for the separation of the tantalum and hence also of the protoactinium, was as follows :

A little tantalum oxide was added, and the material extracted with hydrofluoric and sulphuric acids. The addition of a few milligrams of thorium and lead nitrates at this stage serves to keep traces of ionium, uranium-X, and radio-lead in the insoluble form. The filtrate was evaporated to dryness, so as to leave the tantalum and protoactinium in an insoluble form, from which impurities, such as iron, zirconia, and the like, may be removed by boiling with aqua regia. So far, all attempts to separate protoactinium from tantalum have failed. By various elaborations of this method, the whole of the protoactinium from pitchblende containing a known amount of uranium was carefully separated, and its α -activity measured.

The preparation of protoactinium furnished an α -radiation which increased with lapse of time. It was assumed and proved that the α -rays of low range initially produced were derived from protoactinium, while the α -rays of longer range were due to the growth of actinium and its decay products. The range of the α -rays of protoactinium in air at 0° and 760 mm. was 3.314 cms. Actinium does not follow H. Geiger and J. M. Nuttall's relation so closely as other radioactive series, and there is a considerable difference in the constants according as actinium-X or radioactinium is taken for the comparison—the former furnishes 1700 years and the latter 260,000 years in the period of average life of protoactinium. The at. wt. and spectrum have not been determined, but all the evidence shows that protoactinium is the ekatantalum of the periodic table or an isotope of that element. If the life period of protoactinium is 1200 years, for each gram of radium in uranium minerals there should be 60 mgrms. of protoactinium; and if the life period is 180,000 years, 9 mgrms.

The putative parent of protoactinium is uranium-Y. As previously indicated, it is not clear if uranium-Y is derived from uranium-I or uranium-II—if the former, the at. wt. of protoactinium will be 234, and of actinium 230; while if uranium-Y is derived from uranium-II, as K. Fajans believes is more probably the case, the at. wt. of protoactinium will be 230, and that of actinium 226. According to these hypotheses, the uranium series furnishes :

A. Piccard suggested that actinium is possibly derived from a third isotope of uranium of at. wt. 239, which does not belong to the uranium family at all, but is a distinct primary radio-element, like uranium or thorium. He suggested the name *actino-uranium*, Act_U , for this hypothetical element. He supported this view by assuming that O. Hönigschmid's value 239.16 for the at. wt. of uranium indicates that the assumed uranium is really a mixture of 92 per cent. of an isotope of at. wt. 238 which belongs to the radium series, and 8 per cent. of one with an at. wt. 240 which would make the at. wt. of protoactinium 236, and that of actinium 232. H. Geiger and J. M. Nuttall's curves also show that the three series are not superposed, but furnish parallel lines indicating that each of the three is an independent primary series. The constants are the same for each series, but different for different series. F. Soddy objects that the ratio of actinium to radium in uranium minerals is nearly constant, and this would mean the accepting of the unlikely chance that actino-uranium has the same period as uranium-I. These possibilities can be settled when the at. wt. of actinium or protoactinium has been determined. A. Piccard's hypothesis is supported by E. Q. Adams. E. Marsden and A. B. Wood's diffusion experiments showed that the at. wt. of actinium emanation is 232; this would make the at. wt. of actinium itself 240—rather greater than uranium—on the assumption that 8 units are to be added for the α -particles of radioactinium and actinium-X. A. Smekal discussed the atomic structure of the parents of radioactinium.

In his investigation on the relation between the actinium and uranium series, O. Hahn³ encountered a new radioactive substance which is separated with proto-actinium, and the two radioactive substances are isotopic. The isotope of proto-actinium was provisionally called **uranium-Z**, U_z . It has a half-life period of 6.7 hrs. and gives off complex α -rays which are half absorbed by layers of aluminium 0.014 to 0.12 mm. thick. Only small proportions are present, and the intensity of its radiations is about 0.25 per cent. of that of U_x , that is, $U_x + U_{xz}$. Assuming that uranium-Z is not derived from uranium-X, whereby both pass into uranium-II by the loss of β -rays, it is suggested that there is possibly a new uranium-III series analogous with the uranium-I series, just described. The hypothetical uranium-III is said to be analogous with uranium-I, and to have an at. mass of 240; and it furnishes uranium- Z_1 and uranium- Z_2 analogous with uranium- X_1 and uranium- X_2 respectively: $U_{III} \xrightarrow{240} U_z \xrightarrow{236} U_{II} \xrightarrow{236} U_{IV} \xrightarrow{236} ?$ It is considered to be improbable that uranium-I represents the mother substance of uranium-Z, and that the latter is derived from the former by the loss of a particle of mass 3. M. C. Neuberger suggests the alternative schemes:

but prefers the latter. The subject has also been discussed by A. Smekal, and O. Hahn; the latter said that the suggestion of M. C. Neuberger is improbable and lacks experimental foundation.

§ 13. The Decay Products of Actinium

While studying the radioactivity of a preparation of actinium freed from actinium-X, O. Hahn¹ found that the activity increased to a maximum much more slowly than would be expected if actinium were transformed directly into actinium-X. He showed that not actinium but another product, which he called **radioactinium**, RaAc , is the direct parent of actinium-X; and that the first product of the decay of actinium is probably radioactinium. This product concentrates in the first fractions when a soln. of an actinium salt is fractionally precipitated with ammonia; and by successive precipitations it is possible to obtain radioactinium almost free from actinium and actinium-X.

Radioactinium is also precipitated with sulphur when a soln. is boiled with an excess of sodium thiosulphate. The sulphur is expelled from the precipitate by heat. F. Giesel, M. Levin, and A. Fleck obtained it by adding a little thorium salt to an acid soln. of a preparation of actinium, and boiling with an excess of sodium thiosulphate; the precipitated basic thorium thiosulphate carries down some radioactinium. O. Hahn and M. Rotenbach used a zirconium salt in place of the thorium salt—*vide* purification of actinium. The latter is also deposited on charcoal when the soln. is shaken therewith. H. N. McCoy and E. D. Leman prepared radioactinium, by adding a trace of a thorium salt to the soln., and precipitating the latter by

FIG. 16.—H. Geiger and J. M. Nuttall's relation between the Range of the α -rays and the Period of Transformation.

hydrogen peroxide at 60°. A. Fleck discussed the isotopy of uranium-X, thorium, and radioactinium.

A. S. Russell and J. Chadwick thought that they had resolved radioactinium into two components, radioactinium-I with a half-life period of 19.5 days and radioactinium-II with a half-life period of 13 hrs.; but O. Hahn and L. Meitner could not establish this hypothesis, and they believed that the alleged radioactinium-II is really thorium-B, which has a half-life period of 10.6 hrs., and might easily be present in the products.

Radioactinium is not appreciably volatile at a red heat under ordinary experimental conditions. It emits α -, β -, and γ -rays. The α -rays were found by H. Geiger and J. M. Nuttall to have a range of 4.36 cms.; H. N. McCoy and E. D. Leman, 4.17 cms.; and S. Meyer, V. F. Hess, and F. Paneth, 4.2 cms. to 4.60 cms. in air at 15° and normal press. In general, the range of the α -particles in air is directly proportional to the absolute temp., and inversely proportional to the press. E. Rutherford found the velocity to be 1.68×10^9 cms. per sec. O. von Baeyer, O. Hahn and L. Meitner found the magnetic spectrum of the β -rays showed rays with a velocity, V , of 1.14×10^{10} , 1.26×10^{10} , 1.47×10^{10} , and 1.59×10^{10} cms. per sec., or the velocity is equal to the fractional part, V/V_∞ 0.38, 0.42, 0.49, 0.53 of the velocity of light, V_∞ . The coeff. of absorption of the β -rays in aluminium is 175 cms. The absorption coeff. of the γ -rays is 25 and 0.19 cm^{-1} of aluminium. The product of the decay of radioactinium is actinium-X. The rate of formation of radioactinium from actinium is shown in Fig. 17, calculated from $\text{RaAc} = 1 - e^{-\lambda_1 t}$, where $\lambda_1 = 0.0356$ day, when $t=0$, $\text{Ac-X}=0$, and $\text{RaAc}=1.00$. The rate of decay of radioactinium is shown in Fig. 18, calculated from $\text{RaAc} = e^{-\lambda_1 t}$. According to H. N. McCoy and E. D. Leman, the half-life period of radioactinium is 18.88 days or 4.1×10^7 secs.; O. Hahn gave 19.5 days or 4.25×10^7 secs. There is a discrepancy between the life period calculated by H. Geiger and J. M. Nuttall's equation. This is taken

to indicate that radioactinium is not homogeneous, and, by analogy with thorium, it is possible that a meso-product is present. The average-life period is 21·8 days to 27·24 days. The radioactive constant $\lambda = 4\cdot25 \times 10^{-7}$ secs. or $\lambda = 4\cdot10 \times 10^{-7}$ secs. or 0·0356 day.

FIGS. 17 and 18.—Formation and Decay Curves of Radioactinium and Actinium-X.

About the same time, F. Giesel,² and T. Godlewsky separated a product, called **actinium-X**, AcX, from actinium preparations by the precipitation of the actinium with ammonia, the actinium-X remains in soln. It was at first regarded as the decay product of actinium, and by analogy with the radioactinium substance first derived from uranium, it was called actinium-X. Actinium-X is derived from preparations of actinium which have stood many months in a closed vessel so that it is in equilibrium with its decay products. F. Giesel, S. Meyer and E. von Schweidler, and O. Hahn obtained it by recoil from radioactinium on a negatively charged plate. T. Godlewsky obtained it by precipitating actinium and radioactinium from a preparation of actinium by ammonia, the actinium-X remains in the filtrate. To ensure the efficacy of the process, O. Hahn and M. Rotenbach allowed the filtrate to stand two hours on a water-bath, acidified the soln., and re-precipitated by adding a little ferric salt and then ammonia. A. Debierne found that when barium is precipitated as sulphate in a soln. containing actinium, a radioactive substance is co-precipitated which decays with time. This is now thought to have been actinium-X. H. N. McCoy and E. D. Leman recommended adding a little barium salt to the filtrate, and removing the actinium-X from the soln. by co-precipitation with barium sulphate; or else evaporating the filtrate to dryness, and heating the residue to expel the other decay products, since actinium-X is not volatile at a red heat. H. N. McCoy and E. D. Leman also separated actinium-X by adding a little thorium salt to the soln., and precipitating the thorium with hydrogen peroxide. The precipitation was repeated a number of times, actinium-X and thorium-X remain in the soln. If an ammoniacal soln. of an actinium preparation is electrolyzed, actinium-X, actinium-A, and actinium-B are deposited on the cathode.

Actinium-X behaves like radium in many reactions, and D. Strömholm and T. Svedberg emphasized the analogies between actinium-X and thorium-X. They are indistinguishable as regards chemical properties, and probably both belong to the group of alkaline earths. G. von Hevesy's diffusion experiments show actinium-X to be bivalent. Actinium-X nitrate crystallizes isomorphously with barium nitrate. It is not volatile at a red heat. Its parent is radioactinium and its decay product is actinium emanation. The rate of formation of actinium-X from radioactinium is shown in Fig. 17, calculated from

$$\text{Ac}_X = 0\cdot596 \left(1 + \frac{\lambda_1}{\lambda_2 - \lambda_1} e^{-\lambda_2 t} - \frac{\lambda_2}{\lambda_2 - \lambda_1} e^{-\lambda_1 t} \right)$$

where the constants are $\lambda_1 = 0\cdot0356$ day and $\lambda_2 = 0\cdot0597$ day, and at $t=0$, $\text{RaAc} = 1\cdot00$, and $\text{AcX} = 0$. The rate of decay of actinium-X is shown in Fig. 18, calculated from

$$\text{Ac}_X = \frac{1}{\lambda_2 - \lambda_1} (e^{-\lambda_1 t} - e^{-\lambda_2 t})$$

At the time $t=21.44$ days, the number of atoms of actinium-X present is a maximum. H. Geiger and J. M. Nuttall found that the α -rays emitted by actinium-X have a range 4.40 at 15° and 760 mm. press., and the initial velocity computed by E. Rutherford is 1.65×10^9 cms. per sec.; S. Meyer, V. F. Hess and F. Paneth observed the range 4.26 cms. and initial velocity 1.63×10^9 cms. at 15° . For the half-life period, S. Meyer and E. von Schweidler obtained 11.8 days; O. Hahn and M. Rotenbach, 11.6 days; and H. N. McCoy and E. D. Leman, 11.2 days; the average-life period is 16.45–16.7 days; and the decomposition constant $\lambda=7.04 \times 10^{-7}$ secs. or 0.0597 day.

F. Giesel³ discovered in 1902 that actinium preparations gave off an emanation which was also studied by A. Debierne. Actinium emanation, AcEm, is an inert gas which changes very rapidly—*vide supra*, the proportions of actinium. On account of its short life, the gas has not been isolated in a pure state. It can be removed from actinium soln. by the passage of a rapid stream of air or other gas; it is also readily evolved from most solid preparations of actinium—particularly actinium-lanthanum oxide, hydroxide, oxalate, nitrate, manganite, fluorosilicate, sulphate, etc. Raising the temp. also favours the evolution of the gas. H. Herschfinkel has made observations on this subject.

F. Giesel showed that actinium emanation behaves like a gas. It excites the phosphorescence of barium cyanoplatinate and zinc sulphide. A. Debierne measured the half-life period of decay of actinium emanation and found it to be 3.9 secs.; and O. Hahn and O. Sackur obtained a similar result, and showed that the periods from F. Giesel's emanation, and A. Debierne's actinium were identical. The actinium emanation has virtually disappeared in one minute. S. Kinoshita, and P. B. Perkins, found the half-life period to be 3.92 secs., and M. S. Leslie, 3.91. This gives for the average-life period, 5.55 secs.; and for the radioactive constant, 0.18 sec. F. Giesel said that the emanation is positively charged, but in view of the short period of decay, it is possible that the effect was produced by some of the products of decay. From the effects on the ionization of gases, H. L. Bronson inferred that the emanation in decomposing gives off two α -particles for each α -particle given off by the active deposit in equilibrium with the emanation. This was confirmed by H. Geiger and E. Marsden, and it shows that either the emanation gives off two α -particles or there must be an intermediate α -ray radiating product. H. Geiger showed that the last hypothesis is correct, and the half-life period of this intermediate product is 0.002 sec. The decay of actinium emanation is attended by the emission of α -particles which, as A. Debierne, and F. Giesel showed, furnish helium gas. The range, R , of the α -particles in air at 15° was found by O. Hahn to be 5.8 cms.; S. Meyer, V. F. Hess, and F. Paneth, 5.57 cms.; and H. Geiger, 5.7 cms.; at 0° , H. Geiger and J. M. Nuttall found 5.4 cms. The initial velocity, V , of the α -rays, calculated from $V^3=1.33 \times 10^{27}R$, is 1.93×10^9 cms. per sec. S. Meyer and co-workers found 1.78×10^9 cms. per sec. H. Geiger and J. M. Nuttall's relation between the radioactive constant, λ , and the range, R , is shown in Fig. 11. H. A. Wilson's relation $\log \lambda - \log R = a + bR^{-\frac{1}{2}}$, where a and b are constants; and R. Swinne's relation $\log \lambda = a + bV$, where a and b are constants, are also in agreement with observations on actinium emanation. The kinetic energy of the α -rays is 1.15×10^{-6} ergs.

W. Ramsay, and O. Hahn said that emanation rises in air as if it were specifically lighter than that menstruum, but this may be due to its having been explosively ejected from the solid, or to the emanation being hotter than the ambient air. A. Debierne measured the coeff. of diffusion, K , of actinium emanation, and found 0.112; for carbon dioxide, the coeff. was 0.142; hence, from Graham's diffusion law, the mol. wt. of radium emanation is about 70. This number is very improbable. S. Russ observed for the coeff. of diffusion in air, 0.096–0.122; in hydrogen, 0.330; in carbon dioxide, 0.073; in sulphur dioxide, 0.062; in argon, 0.106–0.109. For the effect of press. p mm., on the coeff. of diffusion, K , he found:

p	.	.	.	14	41	80	155	371	558	764
K	.	.	.	7.81	2.37	1.16	0.582	0.248	0.167	0.125
pK	.	.	.	109	97	93	90	92	93	95

and from a comparison of the coeffs. of diffusion, he found the mol. wt. of thorium emanation to be 1.42 times that of actinium emanation. G. Bruhat found that the effect of temp. and press. of the coeff. is such that $pK/T^2 = \text{a constant}$:

p mm.	760	367	209	127	97	52	36	25	9
θ	15	15	13.5	16.3	14.8	15	16	13	12.3
K	0.112	0.245	0.404	0.55	0.93	1.62	2.29	3.65	9.1
$(pK/T^2) \times 10^3$	10.2	10.3	10.2	8.5	10.8	10	10	11	10

The average of the constant is 0.00101; and therefore for $p=760$, and $\theta=15^\circ$, $K=0.113$. The mean value of S. Russ is 0.115 between 10° and 18° ; hence, all three workers obtained approximately the same value for the diffusion coeff. of actinium emanation in air. For the ratio $K_{\text{CO}_2}/K_{\text{air}}$, G. Bruhat found 0.68, and S. Russ, 0.76; for $K_{\text{H}_2}/K_{\text{air}}$, G. Bruhat gave 3.65, and S. Russ, 3.44. For other materials, G. Bruhat found for ratios of the diffusion constants of the following vapours in the gases named:

	Ether.	Methyl alcohol.	Ethyl alcohol.	Formic acid.	Acetic acid.	Ethyl formate.	Benzene.	Water vapour.	Carbon dioxide.
CO_2/Air	0.71	0.66	0.67	0.67	0.67	0.67	0.70	0.67	—
H_2/Air	3.8	3.8	3.7	3.9	3.8	3.9	3.5	3.5	3.8

For actinium emanation, the values are 0.68 and 3.7 respectively, thus showing that the emanation behaves like an ordinary gas. M. S. Leslie also determined values of p and K , and obtained 0.098 for the value of K at 15° and 760 mm. The result is dependent to some extent on the form of the apparatus. With thorium emanation, the corresponding value was 0.085. Hence, the mol. wt. of the two emanations are not very different. The mol. wt. calculated from the diffusion coeff. are too small in the case of radium, thorium, and actinium emanations. It has not yet been proved that Graham's law of gaseous diffusion is applicable to the case of an exceedingly small proportion of a radioactive gas diffusing into an enormous proportion of another gas. K. Fajans concluded that radium and actinium emanations have the same at. wt. E. Marsden and A. B. Wood obtained the mean value 232 for the at. wt. of actinium emanation, from diffusion in vacuo.

E. Goldstein observed the condensation of actinium emanation at the temp. of liquid air, and E. Henriot found that at -143° , the vap. press. is imperceptible. S. Kinoshita found that condensation begins at -120° , and is complete at -150° . E. Goldstein found the b.p. to be -65° . G. von Hevesy measured the solubility of actinium emanation in different liquids, and found the order with increasing solubility to be the same as for niton. Hence, he concluded that actinium emanation belongs to the same group of inert gases as niton. If the solubility of actinium emanation in water is unity, that in a sat. soln. of potassium chloride is 0.9, in conc. sulphuric acid, 0.95; and in

Ethyl alcohol.	Amyl alcohol.	Benz-aldehyde.	Benzene.	Toluene.	Petroleum.	Carbon disulphide.
1.1	1.6	1.7	1.8	1.8	1.9	2.1

The partition coeff. between water and air is about 2; with thorium and radium emanations, the values are respectively 1.0 and 1.3. F. Giesel found that thin celluloid arrests the emanation. According to G. von Hevesy, wood charcoal absorbs the emanation greedily; at 18° the partition coeff. between carbon and the gas phase (with hydrogen is above 20), and he gave the following comparison:

Helium.	Argon.	Actinium em.	Thorium em.	Radium em.
2	12	20	50	100

The parent of actinium emanation is actinium-X, and its immediate successor is actinium-A, which in turn passes into actinium-B, actinium-C and -C', and actinium-D. As in the case of radium, actinium can under certain conditions impart a temporary radioactivity to bodies in its neighbourhood. A substance exposed for some time in the presence of actinium behaves as if its surface were coated with an invisible film of radioactive matter. This *induced or excited radioactivity* is derived

from the transformation of actinium emanation. The surface of a body exposed to the emanation becomes coated with an invisible film of radioactive matter, called, for convenience, the *active deposit of actinium*. This deposit emits α -, β -, and γ -rays. To obtain the active deposit, a current of air laden with the emanation is passed through a metal cylinder provided with a metal electrode held axially in position, and insulated from the cylinder by rubber-stoppers. If a potential of about 50 volts is maintained between the central negatively charged electrode and the positively charged cylinder, the active deposit collects on the electrode. The distribution of the active deposit on an electric field has been studied by E. M. Wellisch,⁴ S. Russ, H. T. Brooks, W. T. Kennedy, J. C. McLennan, and H. P. Walmsley. According to A. N. Lucian, in dust-free dry air, (i) the percentage of actinium active deposit collected on the cathode increases with increasing potential to a definite limit of 95 per cent. as the maximum, the remaining 5 per cent. consisting of neutral particles, arrive at the electrodes by diffusion. (ii) No negative particles take part in the distribution. (iii) For lower values of the cathode deposit, the formation of neutral deposit particles results both by volume recombination and columnar recombination of the positively charged particles with negative ions. Both types of recombination occur at a faster rate for the deposit particles than for ordinary positive ions, due to their larger mass and size and slower speed. In all respects the actinium active deposit behaves, qualitatively at least, like that of radium. It is supposed that the recoiling deposit particle, in its collision with the molecules in its path, expels from them negative electrons with much greater velocity than is imparted to the positive ion, so that the recoil particle is surrounded by an overwhelming majority of positive ions, and there is a greater probability that it will emerge positively charged than otherwise. The fact that the limiting value for the cathode deposit is for actinium (95 per cent.) greater than for radium (98 per cent.) is what is to be expected from the fact that the actinium-A atom recoils with a greater velocity than the radium-A atom.

As previously indicated H. L. Bronson found that twice as many α -particles were expelled from actinium emanation as were expelled by actinium-C in equilibrium therewith. H. Geiger and E. Marsden noted that the α -particles from actinium emanation appeared as doubles, indicating either that the atom in breaking up emits two α -particles, or that the emanation gives rise to another α -ray product which is very rapidly transformed. The latter hypothesis was established. The two α -particles follow one another with less than $\frac{1}{10}$ th sec. interval. The manner in which the α -ray activity of the active deposit varies with time depends on how long is taken to collect it; if under 10 secs., the activity increases slightly with time, reaches a maximum in 7 mins., and then decreases according to an exponential law; while if over 10 secs., H. T. Brooks observed no initial rise in the α -ray activity. The first transient product of the decay of actinium emanation is a solid, but with a very short life, so that it is usually associated with the emanation. It is called **actinium-A**, AcA. The very short life of actinium-A does not allow it to be isolated and studied in the ordinary way. H. G. J. Moseley and K. Fajans deposited the active matter from actinium emanation on the face of a negatively charged rapidly rotating disc; the radioactivity of the deposit was examined at different angular distances by electrical methods. It was thus found that actinium-A emits α -rays, and that its half-period is 0.002 sec. Actinium-A has the shortest life of any of the radioactive elements yet observed. According to S. Meyer and co-workers, the range of the α -particles in air at 15° is 6.27 cms.; while, according to H. Geiger and J. M. Nuttall, the range is 6.5 cms. at 15°. The average-life period is 3×10^{-3} secs., and the radioactive constant $\lambda = 346$ secs.

L. Meitner found that if an acid soln. of the active deposit of actinium is electrolyzed with silver electrodes, actinium-B, and -C with an excess of actinium-A, is deposited on the cathode. It is thought that actinium-A is chemically analogous with radium-A and thorium-A, and isotopic with polonium. Its nearest companion in the periodic table is tellurium.

Actinium-A is very rapidly changed into **actinium-B**, AcB. This product was discovered by A. Debierne and called actinium-A; what is at present known as actinium-A was discovered later. The changed notation is due to E. Rutherford and H. Geiger. Actinium-B passes into **actinium-C**, AcC, discovered by E. Rutherford, and H. T. Brooks in 1904. It was first called *actinium-B*. H. T. Brooks found that the activity curves of the active deposit of actinium depended greatly on the time of exposure. The activity at first increases, passes through a maximum, and decreases according to an exponential law with a period of 36 mins. H. L. Bronson measured the activity curve for short exposures. This is shown in Fig. 19, where the maximum activity is taken at 100. E. Rutherford showed that the curve is characteristic of one involving two products, one emitting α -rays, the other no α -rays. The decrease in activity fixes the period of one of these products at 36 mins. and $\lambda=0.0192$ min. H. L. Bronson found that $\lambda_2=0.322$ min. for the other, or the period of the second product is 2.15 mins. H. T. Brooks showed that in the electrolysis of the active deposit of actinium, an α -ray product was obtained with a half-life period of 1.5 min. S. Meyer and E. von Schweidler showed that when a platinum plate is coated with the active deposit and heated to a bright red heat, the residual matter emits α -rays and decays with a half-life period of 1.5 min. O. Hahn and L. Meitner further showed that the residual α -ray product had a half-life period of 2.15 mins. Hence, the product with a half-life period of 36 mins., with no α -rays, is actinium-B, and it volatilizes at a high temp., while the α -ray product, which does not volatilize, is actinium-C. M. Levin showed that actinium-B begins to volatilize at 400° , and it is completely volatilized in 10 mins. at 750° , in 4 mins. at 900° , and in about half a minute in a blowpipe flame. Actinium-C is not perceptibly volatilized below 700° . A. Fleck discussed the isotopy of radium-B, and actinium-B; and the possible isotopy of thorium-C, radium-C, and actinium-C.

FIG. 19.—Decay Curve of the Active Deposit of Actinium.

A. Debierne first supposed it to be rayless; but O. Hahn and L. Meitner showed that it emits feeble β -rays which have an absorption coeff. in aluminium of 10^3 cms.⁻¹, and a velocity of 1.80×10^{10} to 1.98×10^{10} cms. per sec., or 0.63 when the velocity of light is unity. Actinium-B was also found by E. Rutherford and H. Richardson to emit γ -rays with an absorption coeff. in aluminium of 120, 31, and 45 cms.⁻¹. The half-life period of actinium-B by A. Debierne is 40 mins.; by H. T. Brooks, 41 mins.; by J. Elster and H. Geitel, 34.4 mins.; by S. Meyer and E. von Schweidler, 35.8; H. L. Bronson, 35.7; O. Hahn and O. Sackur, 36.4 mins.; by T. Godlewsky, 36 mins.; by V. F. Hess, 36.07 mins.; and by H. N. McCoy and E. D. Leman, 36.2 mins. The mean value is 36 mins.; the average-life period is 52.1 mins.; and the radioactive-constant $\lambda=3.20 \times 10^{-4}$ secs. Actinium-B is isotopic with lead, and its chemical properties resemble those of lead. L. Meitner deposited it electrolytically from soln. of its salts—*vide supra*—and if a nickel plate be dipped in a boiling feeble acid soln. of the active deposit of actinium for one to two minutes, actinium-B is deposited on the metal. After actinium-B has been volatilized in air, H. Schrader found the product to be much less volatile, and it can be condensed on a surface at 1000° ; in an atm. of hydrogen, the condensation occurs several degrees lower than in air; this is presumably due to the formation of an oxide. Again, if the active deposit be exposed to bromine vapour, to chlorine, to hydrogen bromide, or to hydrogen iodide for 10–15 mins., the velocity of actinium-B is augmented. The last

two gases cause actinium-C to become more volatile, and after treatment with hydrogen iodide, actinium-C is more volatile than actinium-B. Exposure to hydrogen chloride does not affect the volatility, but if the active deposit which has been exposed to hydrogen chloride be treated with water, nearly all the actinium-B is dissolved, but no actinium-C. Actinium-B is readily dissolved by hydrochloric acid. If the active deposit of actinium be immersed for one minute in 0.001*N*-hydrochloric or sulphuric acid, 80–85 per cent. of the actinium-B is dissolved, and no actinium-C.

E. Rutherford and H. T. Brooks separated actinium-C by the electrolysis of a boiling hydrochloric acid soln. of actinium-B or of actinium-X between platinum electrodes. As indicated above, S. Meyer and E. von Schweidler, and M. Levin found that at about 700°, actinium-B volatilizes from a film of the active deposit of actinium on platinum, leaving actinium-C behind. Actinium-C is said to be isotopic with bismuth. It emits α - and β -rays which, according to H. Geiger and J. M. Nuttall, have a range of 5.40 cms. in air at 15°, and an initial velocity of 1.77×10^9 cms. per sec. at 0°; S. Meyer and co-workers gave 5.15 cms. for the range in air at 15°, and 1.74×10^9 cms. per sec. for the initial velocity at 0°. H. T. Brooks, H. L. Bronson, and O. Hahn and L. Meitner found the half-life period to be 2.15 mins.; the average-life period 3.12 mins., and the radioactive constant $\lambda = 5.33 \times 10^3$ secs.

From the close analogies between actinium-C, radium-C, and thorium-C, it might be anticipated that actinium-C would show peculiarities in its mode of transformation. L. Blanquies found that the variation of ionization along the path of a pencil of α -rays from actinium-C was rather different from the corresponding curves of polonium, and it appeared that actinium-C is complex, furnishing two α -ray products. E. Marsden and co-workers showed that actinium-C decomposed into two radioelements, one **actinium-D**—also called actinium-C''—an α -ray product, and the other, **actinium-C₂**—also called actinium-C'—a β -ray product. The latter transformation represents about 0.15 or 0.2 per cent. of the whole. Actinium-C₂ gives off α -rays with a range of about 6.4 cms. in air at 15°; its half-life period is about 5×10^{-3} secs., its average-life period is about 7×10^{-3} secs., and its radioactive constant $\lambda = 140$ secs. approximately. This product is not very well known. It is assumed to be isotopic with polonium. The changes in the constituents of the active deposit of actinium are therefore summarized:

E. Albrecht obtained for the relation $\text{Ac-C}_2 : \text{Ac-C} = 99.84$. The β -rays and γ -rays of the active deposit of actinium were initially ascribed to actinium-C, but O. Hahn and L. Meitner showed that these rays are derived from the decay product of actinium-C, namely, actinium-D. While the α -ray activity of actinium-C decays with a half-life period of 2.15 mins., the β -ray activity passes through a maximum in about 5 mins., and then decays exponentially with a half-life period of 5.1 mins., the increase in the β -ray activity is due to the formation of actinium-D. O. Hahn and L. Meitner obtained actinium-D by the method of recoil. A negatively charged plate was brought near another parallel plate coated with the active deposit of actinium; in a few minutes, about 20 per cent. of the total amount of actinium-D formed in the interval of exposure is transferred to the recoil plate. Actinium-D in the form of soot was separated from an acid soln. of the active deposit on spongy platinum or carbon. If a platinum plate covered with a film of the active deposit be exposed for a short time to a high temp., the actinium-B and -D are almost completely volatilized, and the remaining actinium-C decays as indicated above.

O. Hahn and L. Meitner found the half-life period of actinium-D to be 5.1 mins., while A. F. Kovarik obtained 4.71 mins.; the corresponding average-life period, 6.8 mins.; and its radioactive constant $\lambda = 2.45 \times 10^{-3}$ secs. T. Godlewsky found the coeff. of absorption for aluminium to be 32.7 cms.⁻¹, and O. Hahn and L. Meitner, 28.5 cms.⁻¹. O. von Baeyer obtained for the magnetic spectrum of the β -rays of the active deposit of actinium, rays with velocities 1.80×10^{10} , 1.98×10^{10} , 2.22×10^{10} ,

and 2.73×10^{10} cms. per sec. E. Rutherford and H. Richardson found the absorption coeff. of the γ -rays of actinium-D to be 0.198 cm.^1 of aluminium. Actinium-D is said to behave chemically like thallium, and to be isotopic with thorium-S and radium- C_2 .

It has been shown that two different lines of argument on the origin of actinium, furnish the at. wt. 226 if derived from uranium-II, and 230 if derived from uranium-I. The former hypothesis is generally accepted, and allowing a reduction of four units for each α -ray transformation, the at. wt. of the other members of the actinium series are readily estimated. This gives the genealogical tree shown in Table VIII. A summary of the radioactive properties of the members of the series is given in Table IX; and the position of the individual members of the actinium series in the periodic table is given in Fig. 20.

FIG. 20.—Position of the Members of the Uranium-Actinium Series in the Periodic Table.

The nature of the end-product of the decay of actinium- C_2 by the expulsion of an α -particle is unknown; the at. wt. of this product, $210 - 4 = 206$, makes it appear as if an isotope of lead is produced. Only 2 per cent. of the parent actinium-C is so converted; the remaining 98 per cent. changes into actinium-D, which, on account of the at. wt. 206, appears as if it is an isotope of lead; and since actinium-D gives off β -rays, it passes into actinium-E, AcE, which, having the same at. wt., is possibly another isotope of lead. It was shown in connection with the end-products of radium that the at. wt. of lead extracted from uranium minerals free from thorium is always less than 207.2, the at. wt. of lead derived from non-radioactive sources. The at. wt. of a number of samples of lead from uranium minerals is 206.04, and if approximately 8 per cent. of this is derived from the actinium branch, and the at. wt. of actinium-E is 210.1, instead of 206, the at. wt. of lead should be 206.4. A. Holmes and R. W. Lawson argue that if the at. wt. of actinium-E is 210, it is an unstable element and is disintegrating, while the end-product of the radium series is accumulating. If actinium-E is slowly disintegrating with the emission of β -rays, it would form an isotope of bismuth; and the at. wt. of bismuth extracted from uranium minerals would not be 208, characteristic of bismuth from non-radioactive sources. If actinium bismuth is unstable the loss of an α -particle per atom would convert it into a thallium isotope, but analyses of uranium minerals for thallium are not available to test the suggestion of A. Holmes and R. W. Lawson.

TABLE VIII.—GENEOLOGICAL TREE OF ACTINIUM FAMILY.

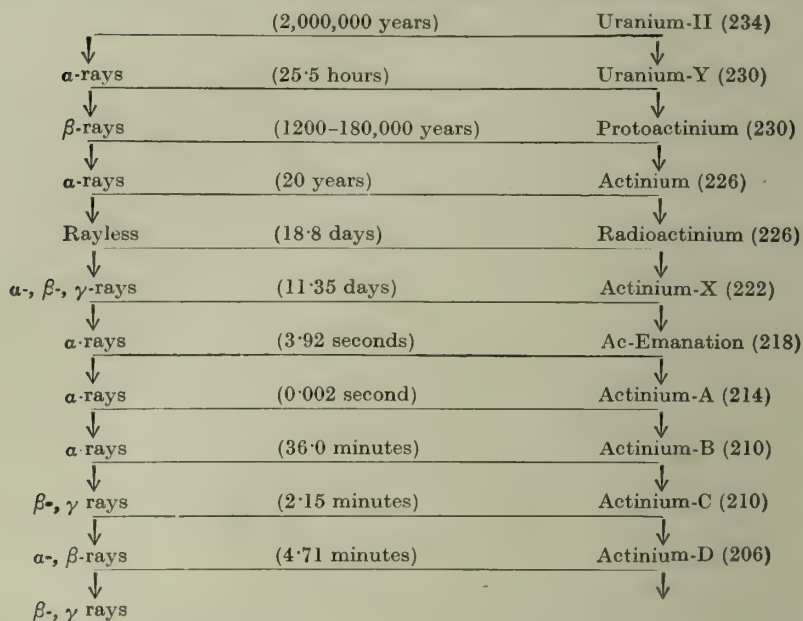

TABLE IX.—PROPERTIES OF THE URANIUM-ACTINIUM FAMILY OF RADIOACTIVE ELEMENTS.

Radioactive element.	Symbol.	Atomic weight.	Half-life period.	Radioactive constant sec.	Radiation.	Range of α-rays cm.	Velocity of α-rays cm. per sec.
Uranium-Y .	UrY	230	25.5 hrs.	7.55×10^{-6}	β	—	—
Protoactinium.	Pa	230	1700–180,000 yrs.	—	—	3.314	—
Actinium .	Ac	226	20 yrs.	—	α	3.56	1.54×10^9
Radioactinium	RaAc	226	11.88 dys.	4.25×10^{-7}	α, β, γ	4.60	1.68×10^9
Actinium-X .	AcX	222	11.35 dys.	7.07×10^{-7}	α	4.27	1.64×10^9
Actinium emanation .	AcEm	218	3.92 secs.	1.77×10^{-1}	α	5.57	1.79×10^9

14. The Transmutation of the Elements—Alchemy

Would to God all men might become adepts in our art, for then gold, the great idol of mankind, would lose its value and we should prize it only for its scientific teaching.—E. PHILALETES (1651).

Alchemy appears to have been a mediæval system of philosophy, and it sought to demonstrate the validity of its doctrines concerning the cosmos by transmuting the baser metals into gold. The following excerpts from alchemical writings¹ will perhaps make clear their ideas on this subject:

Gold is the most perfect of metals because in it Nature has finished her work.—ROGER BACON (1214–1294).

The metals are all essentially identical, they differ only in form. Form brings out the

accidental causes which the experimenter must try to discover and remove.—ALBERTUS MAGNUS (1193–1284).

If by any reason the superfluous matter could be organically removed from the baser metals, they would become gold and silver. Our art only arrogates to itself the power of developing, through the removal of all defects and superfluities, the golden nature which the baser metals possess.—E. PHILALETES (1651).

The mystic gnome who laboured in order to quicken the growth of the metals in mines was a creature of the superstition of the childhood of man. Even the general scepticism of G. Agricola did not protect him from a belief in these demons; and the *knockers* of the Cornish miners, until recently, were very real. G. Agricola wrote as if he knew all about them:

There is the gentle kind of gnome which the Germans as well as the Greeks call *cobalos*, because they mimic men. They appear to laugh with glee and pretend to do much, but really do nothing. They are called "little miners," because of their dwarfish stature, which is about two feet. They are venerable looking and are clothed like miners in a filleted garment with a leather apron about their loins. This kind does not often trouble the miners, but they idle about in the shafts and tunnels and really do nothing, although they pretend to be busy in all kinds of labour, sometimes digging ore, and sometimes putting into buckets that which has been dug. Sometimes they throw pebbles at the workmen, but they rarely injure them unless the workmen first ridicule or curse them. They are not very dissimilar to goblins, which occasionally appear to men when they go to or from their day's work, or when they attend their cattle. Because they generally appear benign to men, the Germans call them *guteli*. Those called *trulli*, which take the form of women as well as men, actually enter the service of some people, especially the *suions*. The mining gnomes are especially active in the workings where metal has already been found, or where there are hopes of discovering it, because of which they do not discourage the miners, but on the contrary stimulate them and cause them to labour more vigorously.

The, perhaps, more philosophical alchemists believed that the perfecting of the metals occurred spontaneously in the bowels of the earth, and Pliny, in his *De historia naturalis* (34, 49, 77 A.D.), tells us that exhausted mines have been closed down to enable the metals to fructify, and so be again profitably worked in a few years' time. They also believed that Nature aimed at the production of gold in mines, and that when she is hindered in her design, the so-called imperfect metals appear. The baser metals were hence called "diseased gold"; mercury was "ailing silver"; copper, iron, lead, and tin were "lepers" which, when cured of their leprosy, would become gold. The alchemists sought to find some means which would hasten the slow natural change so that the transmutation could be conducted in a much shorter time. "It is this means," said Roger Bacon, "which the alchemists indifferently called the elixir, the **philosopher's stone**," etc.

The alchemists wrote in a language we do not now understand. They seem to have associated mystic extravagances with their operations, and to have described their processes in obscure ambiguous jargon, with the result that their readers were "stunned," as R. Boyle expressed it, "with dark and empty words." No wonder that J. J. Pontanus (1520) complained that after travelling through many countries to examine the claims of the adepts, he found many deceivers, but no true philosophers; and N. Lemery that "they professed an art the beginning of which was deceit, the progress of which was falsehood, and the end beggary." Alchemy thus fell into disrepute, for it seemed as if its claims could be established only by chicanery and fraud. Some of the more honest believers explained their failure by asserting that "the art of making gold is beyond the reach of human capacity, and it is made known by God to those alone whom He favours, and who are called adepts." At one period, however, the majority of alchemists did seek to make gold cheaply with the sole object of gaining untold wealth. Failure or delusion was inevitable. Accordingly, the alchemist often misrepresented the truth and degenerated into a charlatan and impostor, pretending, with vulgar frauds, that he had succeeded "in order," says M. M. P. Muir, "that he might really make gold by cheating other people," or else gain notoriety.

It is easy to understand how the belief that the base metals could be converted into gold dominated ancient and mediæval chemistry. Facts were cited in its favour.

The production of beads of silver and gold by the cupellation of metallic lead, and the reduction of metallic ores furnished direct evidence of the metamorphosis of the metals. Again, iron utensils in copper mines became coated with red copper when left in contact with the "mine water," so that the iron was seemingly transmuted into copper; similarly, the formation of white and yellow alloys by mixing copper and certain earths, seemed with the then imperfect knowledge, ample proof of transmutation. The dogma of transmutation thus appeared eminently plausible; it ran counter to no known laws of nature; it rested upon no extravagant assumptions; and it was sanctioned by the highest authorities. The immense labour which must have been expended in the fruitless pursuit of this chemical chimera by the alchemists is appalling. The quest was virtually abandoned with the advent of Lavoisier's balance.

Isaac Newton² gave vague hints of the mutual convertibility of rare and dense forms of matter in some bold speculations he made before the Royal Society in 1675. He said:

Perhaps the whole frame of nature may be nothing but various contextures of some certain æthereal spirits or vapours, condensed, as it were, by precipitation, much after the same manner that vapours are condensed into water, or exhalations into grosser substances, though not so easily condensable; and after condensation wrought into various forms, at first by the immediate hand of the Creator, and ever since by the power of nature, which, by virtue of the command "increase and multiply," became a complete imitator of the copy set her by the great Protoplast. Thus, perhaps, may all things be originated from æther.

A possible dissociation of the elements has also been more or less vaguely suggested by B. Brodie, J. N. Lockyer, T. S. Hunt, F. W. Clarke, etc.

I. Remsen³ has emphasized the fact that the alchemists were the working chemists of their day, and that they laid the foundations of experimental science. He further develops the idea that there is a life after the death of a good doctrine. The phlogiston theory lived in the form of the modern doctrine of free energy, and the idea that there is a relationship between the elements is what I. Remsen calls the spiritual part of alchemy which lives though alchemy is dead. The alchemist's dream of transmutation is very little nearer realization to-day than it was a thousand years ago, for no one has yet really succeeded in transmuting one chemical element into another other than by speculative argument. There is no unimpeachable evidence of a single transmutation of one element into another predetermined by man. Excepting the *interpretation* of the results of E. Rutherford's experiments described below, the words of M. S. Curie are applicable:

En résumé, on peut considérer qu'il n'y a pas encore actuellement de raisons suffisantes pour admettre que la formation de certains éléments puisse être provoquée à volonté en présence de corps radioactifs. La production d'hélium reste acquise; mais elle est reliée à une propriété essentielle des éléments radioactifs et n'est pas influencée par l'intervention de l'expérimentateur.

J. J. Thomson has also stated that all his efforts to decompose atoms by cathode rays or positive rays have failed to produce any conclusive evidence of a transformation. True enough, a few radioactive elements—radium, actinium, polonium, uranium, and thorium—seem to have been discovered in nature, and they are usually stated to be changing spontaneously from one elemental form to another; but no process known to man is able to accelerate or retard, stop or start the metamorphosis. No element has yet been broken down into a simpler substance by a process controllable by man. In the words of Francis Bacon, *natura enim non nisi parendo vincitur*—nature to be conquered must be obeyed.

The alleged transmutation of copper into lithium and sodium by A. T. Cameron and W. Ramsay has been denied by M. S. Curie and E. Gleditsch and by E. P. Perman—the lithium and sodium were derived from the vessels used in the work; the production of neon from radium emanation by W. Ramsay, and W. Ramsay and A. T. Cameron has been denied by E. Rutherford and T. Royds—the neon was

derived from the air which had not been excluded from the apparatus; and the formation of carbon dioxide by the action of radium emanations on soln. of thorium and zirconium by W. Ramsay and F. L. Usher has been called in question by E. Rutherford—the carbon appears to have been derived from the grease used in lubricating the stopcocks. The alleged transmutation of hydrogen into neon, by W. Ramsay, J. N. Collie and H. S. Patterson, and I. Masson, by the action of a stream of cathode rays on hydrogen is considered by J. J. Thomson to be a mal-inference, since the neon is thought to be derived from that originally occluded by the electrodes, or glass vessel, and which is expelled by the bombardment of the cathode rays, but which cannot be removed by the mere application of heat. R. J. Strutt, T. R. Merton, A. C. G. Egerton, and A. Piutti and E. Cardoso could not verify the alleged conversion of hydrogen into neon. E. Briner records some negative attempts to transmute iodine vapour, or a mixture of hydrogen and helium by heating them in an electric arc; and R. W. G. Wyckoff's attempts to transmute lithium were likewise nugatory.

Intra-atomic energy.—The facts previously indicated show that not far from 2,000,000,000 cal. of heat are evolved during the degradation of one gram of radium. This is a quarter of a million times greater than is evolved by the combustion of a similar weight of coal. Hence it is inferred, from the atomic disintegration hypothesis of radioactivity, that the atoms of the radioactive elements, and probably also of other elements, have tremendous stores of potential energy, far greater than is developed during ordinary chemical reactions. The rate of degradation of the energy of the radioactive elements is comparatively slow, and is not available for doing useful work. The rate of evolution cannot be influenced by any known conditions and consequently the transmutation of the elements involves the discovery of methods of controlling these tremendous supplies of energy. Just as the application of a large quantity of electrical energy concentrated at the ends of a pair of platinum wires enabled H. Davy⁴ to decompose the alkali metals, so W. Ostwald, W. Ramsay, and others infer: *if ever one stable element is transmuted into another element, a large quantity of energy in a highly concentrated condition will be required.* This is quite in harmony with the alleged dissociation of the elements in the hotter stars (*q.v.*), where but a few elements are present, and where the temperature has been estimated at 25,000°. The 3000°–4000° obtained in some electrical furnaces appear but puny in comparison with the tremendous natural powers present in the hotter stars. There is some evidence that the swifter α -rays can furnish the necessary energy for atomic disruption.

It has been pointed out that the formation of, say, gold from a metal atomically lighter, say tin, would require the expenditure of so much energy that even if the transformation were accomplished, it could not be a successful commercial process for the production of gold. On the other hand, the formation of gold from an atomically heavier metal, say lead, would liberate such an enormous amount of energy that the gold would be but an insignificant by-product, for the energy liberated during the process would have an enormously greater value than the metal. A. Schack discussed the thermodynamics of atomic energy.

The α -rays of high velocity are powerful agents in producing chemical reaction between molecules, but E. Rutherford has added some evidence that the α -particles can induce even more drastic changes in the atom itself. E. Rutherford,⁵ and H. Geiger and E. Marsden studied the scattering of the α -particles as they pass through matter. In the case of the heavier atoms, like gold, the α -particle suffers no deflection, and the great rarity of large deflections led to the assumption that most of the atomic mass is centred in a relatively small, positively charged nucleus, and in a direct impact the α -particles approaches the nucleus to within about 3×10^{-12} cms. in the case of a heavy atom like that of gold. The large deflections are then attributed to the close impact of the α -particle with the nucleus of the atom—Fig. 3. With light atoms (i) the repulsion is less because of the smaller nuclear charge, and the α -particles can approach nearly ten times as close

as in the case of the more highly charged nuclei of the heavier atoms; and (ii) on account of the small mass of the lighter atoms, they are repelled to greater distances than the heavy ones, and in some cases projected beyond the range of the impelling α -particles. C. G. Darwin concluded that *all light atoms with a single positive nuclear charge, up to and including oxygen, should be repelled by a doubly charged α -particle in the same medium.* If the repelled atom has a double nuclear charge, no atom heavier than helium could be repelled beyond the range of the α -particle without obtaining energy from some other source. E. Marsden estimated that the nuclear encounter of an atom with an α -particle should repel the hydrogen atom with a velocity 1.6 times that of the α -particle; the range of the hydrogen atoms should be four times that of the α -particle; and its kinetic energy 0.64 of that of the α -particle. He was able to detect the propulsion of the hydrogen atoms beyond the range of the α -particle. H. Baerwald, and I. R. Seeliger have discussed the action of α -particles on matter.

E. Rutherford followed up the subject, and showed that the number of hydrogen atoms projected forward by an α -particle of 7 cms. range is thirty times greater than is required by the simple theory of scattering; and this was explained by assuming that the nucleus is distorted by the close approach. In traversing one cm. of hydrogen about 10^5 α -particles propel one swift hydrogen atom, or, out of 10^9 hydrogen atoms ionized, one is propelled forward at a high velocity as a result of direct nuclear impact. The charge of the swift hydrogen atoms is unipolar and positive, and the maximum velocity is in accord with theory, viz. 1.6 times that of the α -particle. Nuclear impact is an atomic phenomenon, and is produced either with an element or with its compounds. It is very difficult to eliminate water-vapour, and possibly other hydrogen compounds, from the field of action; and, in consequence, every source of α -radiation produces some hydrogen atoms moving at a high speed. There is also the possibility that hydrogen particles are shot from the radioactive element much as the α -particles are emitted, but there is no other evidence to support this hypothesis.

E. Rutherford investigated the effect with nitrogen and oxygen gases as well as with hydrogen. Assuming that singly charged particles are formed as a result of the impact, the swift nitrogen atoms should have a range 1.33 times, and the swift oxygen atoms a range 1.12 times, that of the impelling α -particle. The observed range for nitrogen corresponded with theory, but the range for oxygen was little different from that for nitrogen. G. S. Fulcher showed that the swift particles were not likely to be singly charged oxygen or nitrogen atoms because it is not likely that the orbital electrons would be borne along with the impelled atom. It is assumed that the forces binding these electrons to the nucleus are not sufficient to overcome the initial inertia at the moment of impact when they would have to take up a velocity of 10^9 cms. per sec. in less than 10^{-18} secs. Under these conditions it is probable that these electrons would be left behind, or else they would soon be brushed off by contact with the molecules of the gas being traversed. If the swiftly impelled particles were nitrogen or oxygen atoms with multiple charges their range would be shorter than the observed values. G. S. Fulcher therefore assumes that the swiftly impelled particles are really α -particles produced by the disruption of the nitrogen atom by impact. As in radioactive changes, during the atomic convulsion the internal atomic energy becomes available, and it enables the doubly charged helium atoms to be projected beyond the range of the bombarding α -particle. The observed fact is that moving particles are impelled by α -rays, the interpretation by G. S. Fulcher is that the atomic nucleus of a small fraction of the atoms bombarded by α -rays is entirely disrupted into α -particles. The phenomenon thus represents a kind of **artificial radioactivity**.

E. Rutherford placed radium-C as a source of intense α -rays in a metal box, 3 cms. from the end; an aperture in the box was covered by a silver plate eq. in stopping power to 6 cms. of air; and a zinc sulphide screen was placed about 1 cm. distant from the silver plate. If the box be exhausted, the number of scintillations

per sec. on the screen increases; if dry air or carbon dioxide be introduced, the number of scintillations per sec. decreases in the ratio to be expected from the increased stopping-power of the 3 cms. gas column; but if nitrogen from different sources—nitrogen, boron nitride, sodium nitrate, titanium nitride, and paracyanogen—be introduced, the number of scintillations per sec. increases beyond this amount. It is assumed that hydrogen atoms are driven from the nitrogen atoms by the α -rays, because the observed range was too great for the masses of these particles to be greater than those of hydrogen atoms. Hence, it was inferred that **the nitrogen atom is disrupted by being bombarded with α -rays, and that one product of the action is a swiftly-impelled hydrogen atom.**

The deduction that **the long-range particles of nitrogen bombarded by α -rays are hydrogen atoms** is confirmed by estimates of the mass from the magnetic deflection of the particles. E. Rutherford further estimated that in the case of nitrogen only one α -particle in 300,000 succeeds in getting near enough to the nucleus to liberate a swift hydrogen atom with sufficient velocity for it to be detected; and if the entire α -radiation of a gram of radium were absorbed by nitrogen, it would generate about 0.0000005 c.c. of hydrogen per year! E. Rutherford added: It may be possible that the collision of an α -particle is effective in liberating hydrogen from the nucleus without necessarily giving it sufficient velocity to be detected by scintillations. If this should prove the case, the amount of disintegration may be much greater than this estimate.

It would be a bold chemist who would claim to be able to clean his products free from hydrogen or its compounds to anything approaching the implied degree of purity. E. Rutherford and J. Chadwick, however, stated that while the bombarding α -particles have a range of 7 cms., the swiftly moving hydrogen atoms obtained from hydrogen gas and hydrogen compounds have a maximum range of 29 cms. in air, while those from nitrogen have a range of 40 cms. This is taken as evidence that the swiftly moving particles cannot arise from the contamination of nitrogen with hydrogen.

The short-range particles obtained by the action of α -rays on oxygen and nitrogen are thought to be doubly charged helium atoms, and not singly charged or hydrogen atoms; but, instead of the helium particles having a mass 4, their at. wt. is 3. These particles were therefore assumed to belong to an isotope of helium. No long-range particles corresponding to those of mass 1, obtained with hydrogen and nitrogen, were furnished by oxygen; particles of masses 2 and 3 were driven from the oxygen, carbon dioxide, and sulphur dioxide, and E. Rutherford accordingly suggested that the oxygen nucleus is composed of four sub-atoms each of mass 3 and one of mass 4, these with two nuclear or binding electrons giving a net positive charge of 8. The nucleus of nitrogen is similarly composed of four doubly charged helium atoms of mass 3, two singly charged hydrogen atoms of mass 1, and three binding electrons giving a net positive charge of 7. The nucleus atom of carbon is supposed to be made up of four sub-atoms of mass 3 and charge 2, and two binding electrons. M. C. Neuberger calls the assumed element of mass 3—that is, E. Rutherford's X_3 —*isohelium*; and he estimates the most probable value of its at. wt. to be 3.0011, corresponding to the at. mass 4.95×10^{-12} grms.

There are two possible modes of disruption of nitrogen, one giving swift doubly charged atoms of mass 3, and the other giving swift atoms of mass 4. Since the number of the former exceeds the latter five- or ten-fold, it is assumed that the two modes of disruption are independent and do not occur in the same atom.

According to this hypothesis, the atoms of the carbon, nitrogen, and oxygen contain sub-atoms of mass 3; in addition, there are, in the case of nitrogen, substances of mass 1, and in the case of oxygen there is a sub-atom of mass 4. In the case of nitrogen, experiment shows that the sub-atoms of mass 3 are more readily hit and dislodged by the α -particles than the more secluded hydrogen sub-atoms. The results indicate that the elements are built up of nuclei with 1, 2, 3, and 4 atoms,

with even greater masses functioning as secondary units. The nuclei of masses 1 and 2 each carrying one charge are regarded as hydrogen isotopes; those with mass 3 and 4 each carrying two charges are regarded as helium isotopes. E. Rutherford and J. Chadwick found that the long-range particles from aluminium carry a positive charge, and are deflected in a magnetic field to the degree to be anticipated if they are hydrogen nuclei moving with a velocity estimated from their range. E. Rutherford added:

On present views, the neutral hydrogen atom is regarded as a nucleus of unit charge with an electron attached at a distance, and the spectrum of hydrogen is ascribed to the movements of this distant-electron. Under some conditions, however, it may be possible for an electron to combine much more closely with the H-nucleus, forming a kind of neutral doublet. Such an atom would have novel properties. Its external field would be practically zero, except very close up to the nucleus, and in consequence, it should be able to move freely through matter. Its presence would probably be difficult to detect by the spectro-scope, and it may be impossible to contain it in a sealed vessel. On the other hand, it should enter readily into the structure of atoms, and may either unite with the nucleus or be disintegrated by its intense field, resulting possibly in the escape of a charged H-atom or an electron of both.

R. A. Millikan and co-workers said that the passage of an α -ray through hydrogen, carbon, oxygen, nitrogen, chlorine, iodine, and mercury in at least 99 cases out of 100, and probably in all, results in the detachment of a single negative electron from a molecule or an atom. E. Rutherford and J. Chadwick found that the long-range hydrogen particles were furnished by fluorine, aluminium, phosphorus, boron, and sodium; but the numbers from the last two elements were less than from the other three. The following elements were bombarded, but very little if any effect was observed—lithium, beryllium, carbon, oxygen, magnesium, silicon, sulphur, chlorine, potassium, calcium, titanium, manganese, iron, copper, tin, and gold. They added:

It is of interest to note that no effect has been observed in the pure elements—i.e. those without isotopes such as carbon, oxygen, and fluorine, the atomic mass of which is given by $4n$, where n is a whole number. The effect is, however, marked in many of the elements the mass of which is given by $4n+2$, or $4n+3$. Such a result is to be anticipated if atoms of the $4n$ -type are built up of stable helium nuclei, and those of the $(4n+m)$ -type of helium and hydrogen nuclei. . . . No particles have so far been observed for any element of mass greater than 31. If this proves to be general, even for α -particles of greater velocity than those of radium-C, it may be an indication that the structure of the atomic nucleus undergoes some marked change at this point; for example, in the lighter atoms, the hydrogen nuclei may be satellites of the main body of the nucleus, while in the heavier atoms, the hydrogen nuclei may form part of the internal structure. The mass of a helium nucleus is less than that of the four hydrogen nuclei from which it may be supposed to be formed, by an amount $dm = 4 \times 1.0077 - 4.002 = 0.029$. This corresponds with a loss of energy during the condensation of the hydrogen nuclei of $0.029V_{\infty}^2$ per gram atom of helium formed (V_{∞} =velocity of light). Consequently, it is unnecessary to suppose that helium nuclei pre-exist in the nuclei of radioactive elements in order to account for the kinetic energy possessed by α -particles, for part of the energy liberated during the formation of helium nuclei within the atom from pre-existing hydrogen nuclei might be utilized in detaching the α -particles so formed and imparting to them their momentum.

H. Elbertshagen suggested that the atoms of a highly compressed monatomic gas of high at. wt.—e.g. mercury—might be shattered into their components by sparking between electrodes of the highest possible potential. It will be observed that in E. Rutherford's case the disruption is really an inference, since the products have not been isolated in the chemist's meaning of that term. E. Rutherford's test is extremely sensitive, and the trouble with a test like that proposed by H. Elbertshagen, would be to find if anything had happened.

CHAPTER XXVII

THE ARCHITECTURE OF THE ATOM

§ 1. The Mutability of the Elements ; and the Disintegration of Atoms

To inquire whether the metals be capable of being decomposed and composed is a grand object of true philosophy.—H. DAVY (1811).

We must fight against the soporific influence of sham definitions. Especially must we guard against ever allowing them to stand in the way of an inquiry into facts.—A. SIDGWICK.

From the earliest traceable cosmic changes down to the latest results of civilization, we shall find that the transformation of the homogeneous into the heterogeneous is that in which progress consists.—H. SPENCER.

IN 1888, A. Grünwald ¹ defined chemical atoms as follows :

A chemical atom is a complex of exceedingly many movable particles, which are elastic, but so intimately connected together that no chemical process which comes under our consideration is capable of severing this union and breaking the atom into fragments. The parts of the atom are not conceived of as absolutely immutable any more than the atom itself, but as capable within finite limits of undergoing modifications, which have definite relations to their mutual reactions.

This statement is very near what would be written to-day as an introduction to modern views on the structure of the atom. Near the close of the nineteenth century, G. le Bon ² suggested that Becquerel's rays are due to the emission of particles which attends the liberation of *l'énergie intra-atomique* owing to *la dissociation de la matière*. This type of hypothesis is that generally employed at the present day. Many objections were raised at first. It was said that if atoms disengage heat in the process of self-destruction, they are endothermic and, by analogy, should be excessively unstable ; on the contrary, the atoms are the most stable things in the universe. P. Painlevé added that a combination which is so extraordinarily stable, and yet so extraordinarily endothermic, is something which contradicts not only the principle of the conservation of energy, but the whole body of facts which up to recent times have been scientifically established. A. Gautier, and A. Despaux argued in an analogous way.

Near the beginning of the twentieth century, many hypotheses were suggested to explain the phenomena associated with radioactivity :

J. Perrin ³ likened an atom to a miniature planetary system, and assumed that atoms more distant from the centre might escape from the central attraction and produce the phenomena of radioactivity. H. Becquerel assumed atoms to consist of positively and negatively charged particles moving in a system with different velocities, and when projected from the system gave rise to radioactivity. P. Curie at first regarded the emanation of radium as immaterial, consisting of centres of energy attached to gas molecules. P. and M. S. Curie assumed each atom acted as a constant source of energy which was derived from the potential energy of the atom, or the atom might act as a mechanism which instantly regained from the surrounding air the energy it had lost. P. Curie and A. Laborde assumed the heat energy might be derived from the breaking up of the radium atom, or from energy absorbed by radium from some external source. J. J. Thomson suggested that that energy was derived from a change within the atom—the contraction of the atom, for instance, would release a large store of energy. W. Crookes pointed out that if the moving molecules of the air impinged on the molecules of the radioactive substances, and were released with a lower velocity, the energy of radioactive substances could be derived from the atm. F. Re suggested a theory in which the contraction of nebulous matter formed atoms with the evolution of energy, and he likened an ordinary atom to extinct suns, while the atoms

of radioactive matter represented a transitional stage. Lord Kelvin suggested that the radioactive matter absorbed unknown radiations from the surrounding air. Analogous suggestions were made by O. J. Lodge, A. Schuster, E. J. Mills, N. Hessehus, J. K. Puschl, and J. W. Mellor. H. E. Armstrong and T. M. Lowry indicated that radioactivity might be an exaggerated form of phosphorescence or luminescence with a slow rate of decay. R. Meldola suggested the *helide hypothesis of radioactivity*. In this, the radioactive elements are supposed to be compounds of helium with other elements—**helides**—and these compounds are further supposed to be undergoing a gradual spontaneous decomposition into simpler substances. This hypothesis was soon abandoned by R. Meldola. J. M. del Castillo advocated a modified form of the same hypothesis, but it has received very little consideration.

Attention has been mainly focused upon an hypothesis, which runs somewhat as follows: Ordinary atoms are small intricate systems of electrons, linked together by forces of tremendous power. The properties of the different elementary atoms are determined by the number and configuration of the infra-atomic electrons. Radioactivity is an atomic property, and it is an effect of the instability of certain atomic systems. The disintegration of the unstable atoms is marked by the emission of rays. The radioactive elements are therefore unstable, and are continually and spontaneously changing by numerous intermediate stages into more stable elements. This hypothesis is sometimes called E. Rutherford and F. Soddy's **theory of the disintegration of the atoms**, because they established its claim to serious consideration, and have done valuable work with its aid. Their hypothesis is now orthodox and fashionable. If this hypothesis should survive that struggle for existence which all neoteric hypotheses must undergo, then radioactivity will be cited as proof of the **devolution of the elements**. Astro-spectral observations leave little room for doubt that in the cooling stars a process of **evolution of the elements** is in progress. This subject has been discussed by J. H. Vincent.

It is further assumed that the radioactive elements are not unique among the elements in containing abnormal stores of internal energy, but—excluding potassium and possibly rubidium—the other elements are either immutable or else they are changing so slowly that no signs of mutation have yet been detected. According to the atom disintegration hypothesis of radioactivity Nature is continually changing the elements with the largest at. wt. such as uranium (238.5) and thorium (232.4) into simpler elements. The latter, in turn, are said to be stable simply because no signs of radioactivity have yet been detected. It is possible that if ever elements existed on earth with larger at. wt., and by inference, with more complex atoms, they have all degraded into simpler forms, and are now probably **extinct elements**, hence, also, it might be inferred that *the most widely diffused elements have small atomic weight*. The gaps which appear in the periodic table also appear significant. The elements with the smallest at. wt., and those which are found in greatest abundance on the earth—hydrogen, helium, calcium, oxygen, sodium, silicon, etc.—are usually considered to be the most stable, and to contain least infra-atomic energy. Hydrogen and helium, occurring in the hottest stars, are supposed to have a tendency to form aggregates, and pass into common terrestrial elements during the cooling of the hot stars. It seems as if uranium and thorium must have been exposed to peculiar conditions—possibly of press. and temp.—whereby they were elaborated beyond the limits of stability, and absorbed stores of energy which are now being slowly released because the conditions necessary for their stability no longer obtain.

It might be asked why the comparatively conspicuous self-destructive activities of radium have not led to its extinction long ago? E. Rutherford estimated that the radium now on earth will be disintegrated and the whole virtually extinct in about 25,000 years. There can thus be little doubt that if there had not been a continuous source of supply, radium would have been an extinct element long ago. The decay of the heaviest known element uranium is so extraordinarily slow that it can just be detected, and a rough estimate made of its life—8,000,000,000 years—as indicated above.

The mode of evolution of the elements hypothecated in the attempt to co-ordinate the results of the spectroscopic study of stars and nebulae, seems to be

supported by a mass of cumulative evidence, and to be inherently probable. It remains to find an adequate explanation to account for the vast stores of energy available in the hotter stars.

We can now see a possible explanation for the inseparable companionship of many elements. The occurrence or distribution of the elements over the earth appears to be an effect of an important genetic law. The approximately uniform quantities of many of the rarer metals in different parts of the earth indicate that these elements are degradation products of more complex elements; and that they, in turn, will probably be degraded into simpler products. The relative speeds of these slow changes determine the amount of each element which can be present on the earth at any given time. This subject has been discussed by W. D. Harkins, J. Waddell, etc.

It may very properly be thought that *a modicum of fact is here entangled with an abnormal amount of speculation*, especially when it is remembered that the experiments have been made upon very minute quantities of material. At first sight, it does appear as if we have developed what A. Smithells⁴ humorously called "a chemistry of phantoms." Thanks, however, to the extraordinary delicacy of the electrometer and of the spectroscope, there is no doubt about the facts, even though but extremely minute quantities of radium are available for experiments. The argument converges on the assumption that radioactivity is an atomic property; this hypothesis, in turn, is mainly based on the indifference of the speed of radioactive changes to external conditions of temp., press., etc. It is therefore pertinent to inquire into the validity of the alternative hypothesis, and ask:

Are the "radioactive elements" really elements, or are they compounds containing helium? As already hinted, the dogma that radium is an element is not so firmly established that there are no reasonable grounds for the exercise of some Cartesian doubt, for, said E. W. Morley, he is wise whose assertions regard the possibility of finding at some time evidence to the contrary. E. Rutherford has said that "since in a large number of cases the transformation of the atoms is accompanied by one or more charged atoms of helium, it is difficult to avoid the conclusion that the atoms of the radioactive elements are built up, in part at least, of helium atoms." As an alternative to Rutherford's atom-disintegration hypothesis, and as a corollary to the inference that the molecules of the argon-helium family are really polyatomic (1. 13, 9), the helide hypothesis assumes that radioactive elements are really compounds of an active form of helium in the same sense that nitrogen chloride may be said to contain the atomic or active form of nitrogen. Ordinary helium, like ordinary nitrogen, is characterized by great chemical inactivity. If this hypothesis be valid, it must be supported by a formidable list of unique hypotheses, for it must be assumed further that (1) the alleged compound—**helide**—is spontaneously decomposing; (2) abnormally large amounts of energy are set free during the decomposition; (3) the emission of radiations accompanies the change; (4) the speed of the decomposition is not affected by any known external conditions; and (5) in opposition to a little circumstantial evidence, that the helium molecule is a complex of atoms, and not monatomic. *Otherwise*, adds H. E. Armstrong: the decomposition of radium regarded as a compound of helide helium is no more remarkable than that of liquid ozone, or of nitrogen chloride! H. E. Armstrong continues:

The atoms of helium and of the allied inert gases are gifted with intense activity far beyond anything we know of, it may well be that when such atoms enter into combination, either with one another or with other elements, the amount of energy set free is very great, and that when they combine with other materials, they may produce changes in properties very different from and far more profound than those we know of at present.

The plausibility of the helide argument turns on this: The greater the amount of hypothetical energy assumed to be required to break down the hypothetical helide molecule into its supposed atoms, the greater the appearance of probability of the argument that radioactive phenomena are chemical in kind. Questions

like these have to be treated more by instinct (or prejudice) than by logic ; and those who do the work must use what hypotheses they find most fruitful.

Naturally, the student of chemistry may be somewhat disconcerted with this apparent attack on what appear to be the essential principles of chemistry. At first sight, it does seem as if we must say "good-bye to the equations of chemistry," because, if the truth about the suspected disruption of atoms be truly vindicated, the fundamental concepts—atom, element, persistence of weight, etc.—must be revised in order to make them harmonize with the facts. The conception of an **element**, given in the first volume, has long held an honoured place in chemical text-books ; and, with this before us, at first sight, it might appear illogical to apply the term to a substance which can be resolved into two or more simpler forms of matter. Any substance which can furnish two or more different elements may seem to have forfeited its place in the list of elements. Some try to evade the difficulty by assuming that there is an agreement among chemists to recognize a substance as an element which, under proper conditions, exhibits a spectrum showing characteristic lines possessed by no other element, and possesses a definite combining weight. Of course, we are at liberty to change our definitions, but, as W. D. Bancroft has said, the only advantage of the new definition is that it enables chemists to say that they have decomposed an element. M. S. Curie stated definitely that radium is not a compound of helium, but the only way she can make radium an element is by changing the old definition so that it shall not include radium. The definition employed in the first volume, however, is elastic enough to cover cases of transmutation, for, *if an element containing but one kind of matter suffered an atomic cataclysm, it might furnish two or more different kinds of matter each of which would be an element because it would contain but one kind of matter.* K. Fajans suggests the definition : "An element is a substance which has not been separated into simpler constituents, and is not known to be a mixture of other substances." Each isotope, on our standard definition of an element, is to be regarded as a definite element ; but if, as is done by F. Paneth, "an element is defined as a substance which cannot be simplified by any chemical process," then isotopes would be regarded as one and the same element, because they cannot be separated ; and a specific at. wt. is not then a characteristic property of an element. F. Paneth further added that an element can consist of similar atoms—*Reinelements, pure elements*—or of atoms differing in weight or radioactivity, or both—*Mischelements, mixed elements*. Some one has suggested that the elements be called *chemical primaries*. We are always loath to multiply definitions, and would much rather condense a number of definitions into one. As already emphasized, the definition must not be taken to imply that the elements are absolutely immutable, although, so far as our present knowledge goes, they are both immutable and primitive in chemical reactions. This subject has also been discussed by R. Wegscheider, and J. Barborovsky.

However paradoxical it may seem, the hypothesis that the **atom** of an element is a most intricate bit of mechanism, a complex aggregate of parts liable to disruption, is now generally accepted. This, however, does not affect the time-honoured definition of an atom. **The atom still remains a veritable unit indivisible in chemical reactions.** Had the facts, speculations, and theories here discussed been treated at the beginning of the first volume, that would not have altered our mode of presenting the facts of material chemistry. According to T. W. Richards, so far as ordinary chemical reactions are concerned :

Our relations with chemical elements primarily concerning us are unchanged by all the fascinating new knowledge. These same old elements remain as permanent as ever they were. . . . The atomic theory is indeed even more convincing to-day with regard to mundane chemical affairs than it was before the dawn of radioactivity.

Suppose an atomic convulsion or cataclysm were to occur so that the complex system of electrons which is supposed to form an atom were to break up into simpler parts ; suppose further some of the electrons grouped themselves into helium, and

the others into some other substance; and let us also assume, for a moment, that some electrons simultaneously escape and are merged into the æther of space, it is then conceivable that there will be an apparent loss of weight. Consequently, while the law of persistence of weight holds good with chemical reactions in which the atoms remain intact, it is quite conceivable that an apparent loss in weight might occur during a radioactive change. The evidence, however, is in favour of the assumption that the law holds good in radioactive changes. The relation of mass to energy is treated in 1. 13, 1. If the products of the disintegration of the atom have mass, it might be inferred that the absolute mass still remains constant, although, if radium be an element, the invariability of mass or weight can no longer be referred back to the constancy of the atom. This visionary phenomenon has been described in order to emphasize the need for care in building rigid, non-plastic concepts and definitions from negative results based on the uncontradicted experience of mankind.

§ 2. The Creation and Annihilation of Matter

Even if we resolve all matter into one kind, that kind will need explaining. And so on for ever and ever deeper and deeper into the pit at whose bottom truth lies, without ever reaching it. For the pit is bottomless.—O. HEAVISIDE.

Things which are seen were not made of things which do appear.—ST. PAUL.

Æther is the parent of all things.—LUCRETIVS (c. 60 B.C.).

In mechanics, the definition of matter is based upon Newton's first law of motion—the law of inertia—where matter is defined as that which requires the expenditure of an external force to change its state of motion. Otherwise expressed, inertia, or helplessness, is a characteristic of every form of matter. No material thing can of itself change its own state of motion, for an external influence is required before such a change can take place. If it be admitted that **any entity which requires the application of a force before it can change its state of motion is a form of matter**, an electron in motion must be a form of matter, because it requires the application of a force to change its state of motion.

The inertia of matter.—This definition is also reversed, and **force is defined to be that influence which is required to change the velocity of any material body**, and it is measured in terms of the **dyne** as unit. A dyne is that force which applied

to a mass of one gram during one second imparts to it a velocity of 1 cm. per sec., or which changes the velocity of the body 1 cm. per sec. when acting for 1 sec. These ideas can be expressed in another form. The inertia of a body is that property of matter which resists change of motion, and it is measured in terms of the force required to produce a change of 1 cm. per sec. in the velocity of the body. Accordingly, *when the action of a force on two bodies produces the same change of velocity per second, their inertia are said to be equal.*

The mass of matter.—A body falling from a height down to the earth's surface—in *vacuo* so as not to be influenced by the resistance of the air—gains in velocity, say, g cm. per sec. If the mass of the body be m , then the force pulling that body down will be measured by the product mg . This is the **weight** of a body; hence the weight of a body is g times its mass. The weight w of a body measures the force by which it is attracted to the earth's surface, whereas mass refers to the quantity of matter m in a body, and is independent of gravitation or weight. Experiments have shown that all material bodies have the same numerical value for g , namely, 981 cms. per sec. when acting for 1 sec. (latitude 45° , and at sea-level). Accordingly, $w=981m$; or the weight of 1 grm. of matter is 981 dynes; or the weight of a body is 981 times its mass; or the mass of a body is $\frac{1}{981}$ of its weight—under standard conditions. The masses of two bodies in the same place must therefore be proportional to their weights. *If in the same locality the action of gravity on two bodies produces the same change of velocity per second, their masses are said to be equal.* This conclusion is in harmony with that deduced in the preceding paragraph, and, accordingly, it has been inferred that **mass and inertia are identical**; meaning that the definitions of inertia and of mass, in the nomenclature of mechanics, are not mutually exclusive.

Electromagnetic mass.—When charges of electricity are set in motion, they act like electric currents, and set up magnetic fields which oppose the motion—E. Lenz's law.¹ An electrically charged body exerts force all round itself, a greater force is required to stop or accelerate an electrically charged particle than when not charged. Otherwise expressed, the inertia of a particle, or its effective mass, is greater when electrically charged. Consequently, *an electrified particle possesses in virtue of its electrical charge, a supplementary inertia of electromagnetic origin.* According to J. J. Thomson, the simple dynamic energy of a charged sphere is $\frac{1}{2}m_1V^2$, where m_1 is the mass, and V the velocity; the supplementary energy required for the magnetic field introduced by a charged sphere of unit radius is $\frac{2}{3}e^2V^2$, where e denotes the electric charge. Adding dynamic and magnetic energies, it follows that the

$$\text{Total energy} = \frac{1}{2}(m_1 + \frac{2}{3}e^2)V^2$$

in which the bracketed term is the effective mass, the energy of the combination; the term $\frac{2}{3}e^2$ is the electric inertia or electromagnetic mass.

Again, when two charged spheres are in rapid motion with the same speed in the same direction, the forces which they exert on one another are equal and opposite; but in all other cases, the force which A exerts on B is not equal and opposite to that which B exerts on A . It is therefore assumed that A and B are in communication with another system, the æther, which is able to store momentum so that when the momentum of the system AB is altered, the momentum which has been lost by A and not gained by B has been stored in the æther. Only when A , B , and the æther are considered as one system can the momentum be regarded as constant. Thus do the experiments of M. Faraday show that *a certain proportion of electrical energy can be located outside matter.* With M. Faraday's conception of tubes of force, endowed with momentum, the energy of a tube of force will belong to the body from which the tube originates; and the electric inertia will be due to the grip of these tubes of force on the æther. In this sense, as J. J. Thomson puts it, *an electrified body is associated with an æthereal or astral body which it has to carry with it as it moves, and which increases its apparent mass.*

J. J. Thomson further showed that when an electrified sphere is in rapid motion, the lines of force have a tendency to set themselves at right angles to the direction in which they are moving; they tend to leave the front and rear, and to crowd into the middle. This increases the electrical potential energy; but the mass of the æther bound by the lines of force is proportional to the electrical potential energy; hence, the electrical mass of a charged sphere in motion will be greater than when the sphere is at rest. The difference is very small when the velocity of the charged body is small, but when the speed approaches that of æther wave motion, the lines of force become equatorial, and the mass indefinitely large. W. Kaufmann tested these deductions with the fast-moving β -particles from radium. He measured the ratio of the electric charge e to the mass m of its carrier for speeds ranging from 2.36×10^{10} to 2.83×10^{10} cms. per sec. Several relations between the mass and speed of the moving particles have been deduced—by J. J. Thomson, O. Heaviside, G. F. C. Searle, etc.—on the assumption that the moving electrode is either (a) rigid, or (b) contractile. W. Kaufmann employed the one deduced by M. Abraham, for rigid electrons, *viz.*

$$\frac{m}{m_0} = \frac{3}{4} \cdot \frac{1}{\beta} \left(\frac{1 + \beta^2}{2\beta} \log \frac{1 + \beta}{1 - \beta} - 1 \right)$$

where m denotes the mass of the electronic particle moving with a velocity V ; m_0 denotes the mass of the electron for slow speeds; and $\beta = V/V_\infty$, where V_∞ represents the velocity of light. W. Kaufmann's results are shown in Table I.

TABLE I.—EFFECT OF VELOCITY OF MOTION ON THE ELECTRICAL MASS OF A PARTICLE.

$V \times 10^{-10}$	$\frac{e}{m} \times 10^{-7}$	m/m_0	
		Observed.	Calculated.
2.36	1.31	1.50	1.65
2.48	1.17	1.66	1.83
2.59	0.97	2.00	2.04
2.72	0.77	2.42	2.43
2.83	0.63	3.10	3.09

Hence, either the value of m increases or the charge e decreases with increasing velocity, for the greater the velocity the smaller the numerical value of the ratio of the electric charge to the mass. The relation

$$\frac{m}{m_0} = (1 - \beta^2)^{-\frac{1}{2}}$$

deduced by H. A. Lorentz for an electron which contracted in the direction of its translatory motion without changing its other dimensions, did not give such good results; but, as M. Planck has emphasized, the experiments probably agree with both formulæ within the limits of experimental error for the β -rays employed. A. H. Bucherer assumed that an electron is spherical when at rest, but when in motion contracts in the direction of its translation, and expands laterally so as to preserve a constant volume; he also tested the constancy of the ratio e/m for the β -rays, and found that the results agreed with the formula for the contractile electron, but not with that for the rigid electron.

W. Kaufmann assumed that the charges on the particles remain constant and invariable, and accordingly, it follows that the electromagnetic mass of the electrons is not constant, but increases rapidly as the velocity is augmented. The greater the speed, the greater the mass; he found that the electromagnetic mass of the

more rapidly moving particles was as much as three times that of the slower moving ones. On J. J. Thomson's hypothesis, this means that the mass of these particles is due to the æther gripped by their fields of force. Further, if any part of the mass of an electron is ordinary mechanical mass, it must be indefinitely small in comparison with that which is of electrical origin, since the electrical inertia of a body depends upon its velocity and approaches infinity when the velocity of the body approaches that of light. It is therefore inferred that if the premises be granted, it follows that the velocity of light is the greatest possible velocity which a body can attain; but no other valid reason has been given for the assertion. The variation in the electromagnetic inertia or mass of a body is the same as if the electrical mass existed alone, and the dynamical mass were virtually zero. Consequently, it has been inferred that (1) the electrons do not possess a material mass in the ordinary sense of the word; and (2) the electrons have no mass other than that which is derived from their motion and electrical charge. If the real mass of an atom is the sum of the positive and negative electrons, and the latter have no material mass, it might be inferred that the positive electrons or the mass of an atom would still remain a constant. H. A. Lorentz, however, has shown that in all probability the mass of all particles will be affected by their translational velocity to the same degree as the electromagnetic mass of the electrons.

If dE/dt denotes the rate at which a black body receives energy; F , the force; and V_{∞} , the velocity of light, J. C. Maxwell, L. Boltzmann, and E. L. Nichols and G. F. Hull showed that $F = V_{\infty}^{-1}(dE/dt)$, which is evidenced as the so-called pressure of radiation. A body subject to the force of radiation, F , will acquire momentum, M , at the rate $dM/dt = F$, and hence $dE/dM = V_{\infty}$, meaning that the rate of acquired energy to the acquired momentum is equal to the velocity of light. By definition, momentum, M , is the product of mass into velocity, or, $dM = V_{\infty} dm$, and substituting for dM in $dE/dM = V_{\infty}$, it follows that $dm = V_{\infty}^{-2} dE$, or, since V_{∞} is known to be 3×10^{10} cms. per sec., *changes of mass are proportional to changes of energy:*

$$dm = 1.111 \times 10^{-21} dE$$

A similar result is obtained for the kinetic energy and mass of a moving body. Hence, *a body which is receiving or emitting radiant energy gains or loses energy in proportion, and by the amount 1.111×10^{-21} grms. for every erg.* This result obtained by G. N. Lewis is the same as that previously obtained by A. Einstein from the electromagnetic theory, and the principle of relativity. With the electromagnetic theory alone, D. F. Comstock obtained a similar result but involving a constant. If the mass of the body be a function of the total energy, any body will weigh more when hot than when cold; more when carrying an electric charge than when neutral; and more when in motion than when at rest. Granting these premises, 68,000 cals., or 2.89×10^{11} ergs of energy, are liberated in the formation of a mol of water; consequently, the change in mass which occurs in the formation of a mol of water is $dm = -3.18 \times 10^{-9}$ grms. This is so small as to be outside the range of experimental verification. These results do not mean that the law of conservation of energy has failed, it is only when restricted systems are considered that there are actual losses; for the energy liberated by a change of mass goes to increase the energy and consequently also the mass of some other body.

Again, it is assumed that electricity is a phenomenon of the æther, and that the atom is built entirely of electrons; consequently, as J. Larmor expressed it: **atoms are forms of æthereal strain, or the material atom is formed entirely of æther,** and has no material substratum. Further, the electrons are supposed to be minute electrified strains, squirts, vortices, swirls, eddies, or whirlpools in the æther. When æther is condensed into vortices it is supposed to acquire a tension decreasing with the distance in all directions, and creating a mutual attraction between any two sets of vortices, which is directly proportional to the product of both the amounts of energy needed for their contraction (mass), and inversely proportional to the squares of the distance between their centres—*i.e.* Newton's formula for gravita-

tion. The intangible, imponderable, all-pervading æther is supposed to be susceptible to the solicitations of gravity, as matter, only when it is stirred into innumerable swirls, which are held together by powerful cohesive forces. Hence, it is said : *æther is the mother of matter* ; for in the æther—

Wrapt in mystic silences and glooms,
The slumb'ring secrets of creation lie.

Some even claim to have created material atoms from immaterial æther, but the claims are somewhat questionable. The stages in the alleged genesis and destruction of matter can thus be symbolized :

Material	Immaterial
$\text{Matter en masse} \rightleftharpoons \text{Molecules} \rightleftharpoons \text{Atoms} \rightleftharpoons \text{Electrons} \rightleftharpoons \text{Æther.}$	

Dematerialization of matter \rightleftharpoons Materialization of æther.

When, therefore, it is assumed that material electrons have been resolved into primitive æther by relieving the strains, or stilling the swirls, it is at the same time assumed that matter can be deprived of cosmical existence, and transmogrified into Nirvanian nothingness. With the annihilation of ponderable matter, the law of the conservation of matter disappears, and apparently the only constant in the universe is nothingness !

The argument turns on the nature of the electrons and of the æther. The æther is assumed to be immaterial, or, as Pythagoras (c. 500 B.C.) expressed it, "a celestial substance free from all perceptible matter." It must be remembered that the æthereal plenum cannot be compared with any known thing. It is utterly beyond the range of our sense perceptions, and as G. le Bon has said, we are related to the æther much as a man born deaf is related to music, or a man born blind is related to colour ; accordingly, no analogy can make such men understand what is a sound or a colour. In the words of T. A. Edison (1892) : "As for the æther which speculative science supposes to exist, I know nothing about it."

§ 3. Thomson's Corpuscular or Electronic Hypothesis of Matter

If we be curious to know what matter is, we plunge at once into that deep which surrounds us on every side, and which never yet was fathomed by human intellect.—J. F. DANIELL.
Liability to error is the price we have to pay for forward movement.—A. SIDGWICK.

No difference other than velocity of translatory motion has been detected in

the properties of negative electrons when produced in many different ways, and from many different gases; and since the mass of a negative electron (corpuscle) is less than that of any known atom, the corpuscle must be a constituent of many different substances; and the atoms of these substances consequently must have something in common. This suggests the idea that the atoms of the chemical elements are built of simpler components, the electrons have thus been regarded as the ultimate sub-atoms or the *Uratomen* of which matter is essentially composed. Since the electron is a constituent of atoms, J. J. Thomson¹ considers that "it is natural to regard the electron as a constituent of the primordial system."

J. J. Thomson's electronic theory of matter is one of the unitary theories. It is based on a suggestion made by Lord Kelvin, in a paper entitled *Aepinus atomized*, that a chemical atom consists of a sphere of uniform positive electrification containing negative electrons of much smaller dimensions embedded therein; it assumes that **each atom of any element consists of a large number of electrons,**

all electrified negatively, and held together by positive electricity equivalent in amount to the sum of the negative charges of all the electrons so as to produce an electrically neutral atom. J. J. Thomson also accepts the atom-disintegration hypothesis of radioactivity.

The distribution of a number of negatively charged particles in a sphere of uniform density has been investigated mathematically by J. J. Thomson. Five is the greatest number of electrons which can be in equilibrium in a single ring. But if other electrons be placed within the ring, a larger number can be maintained in equilibrium in one ring. Thus a ring containing six electrons would not alone be stable, but if a seventh electron be placed within the hexoidal unstable ring, the system will become stable. A greater number of electrons will arrange themselves in a series of concentric rings. Table II illustrates the number of electrons arranged in a series of concentric rings which give

systems in stable equilibrium when the number of electrons in the system ranges from 1 to 58. These suffice to illustrate the principle involved.

The idea was neatly demonstrated by repeating an old experiment due to A. M. Mayer²—the so-called **Mayer's floating magnets**. Small uniformly magnetized needles were thrust through discs of cork, and floated on water so that the negative poles of all the needles floated above the surface of the water while the positive poles were submerged.

FIG. 1.—Mayer's Floating Magnets.

When a positively charged magnetic pole is suspended a little above the surface of the water, these needles arrange themselves like J. J. Thomson's imaginary corpuscles. The diagram (Fig. 1) shows that a group of these needles arrange themselves in water at the apices of a triangle; a group of four needles, at the four corners of a square or as a triangle

with a needle in the middle; if another needle be thrown into the water, the five needles take up positions at the corners of the pentagon or as a square with one in the centre; if another needle be thrown in, five needles form a pentagon as before, but the sixth needle goes to the centre of the pentagon or a triangle with needles at the apices and mid-points is formed; if another needle be introduced, six arrange themselves at the corners of a hexagon, and the remaining needle goes to the centre. Thus, a ring of six needles is unstable if hollow, but it is stable when another is placed inside. This is an important principle in the formation of stable systems of negatively charged electrons. It is obvious that *for stable equilibrium the structure must be substantial; a system with a large number of electrons on the outside, and none within, will be unstable.* R. W. Wood obtained analogous results. A. C. Crehore suspended a number of steel balls of uniform size by means of long thin wires in castor oil, and then charged the balls up to a high potential and allowed them to take up their equilibrium position. The disposition of the balls agrees with that worked out by J. J. Thomson.

There is an important difference between Mayer's floating magnets, Thomson's systems of concentric rings of electrons, and the electrons in a real atom, because the two former are supposed to move in one plane (as on the surface of the water), whereas the electrons of an atom are in motion—possibly revolving in orbits like planets or they may vibrate about stable positions.

The architecture of the atom.—According to Lord Kelvin's hypothesis,³ each atom is a remarkable constellation of electrons ranged in a system of concentric rings all assembled within a sphere of uniform positive electrification. J. J. Thomson showed that although the mass of the negative electron seems to be about $\frac{1}{1700}$ th of that of the hydrogen atom, it cannot be assumed that the hydrogen atom contains about 1700 negative electrons, unless the mass of the positive electron be ignored. The surface of the imaginary sphere may be regarded as the limiting surface of the atom. The electrons are further assumed to be in rapid orbital motion about the centre of the sphere. They are subject to the mutual repulsion of the negative electrons and the attraction of the total positive charge. Positive electricity never appears apart from matter, so that it is always associated with the atom itself. J. H. Jeans, N. Bohr, G. A. Schott, etc., have studied the emission of series of spectral lines by atoms made up of rings of revolving electrons. H. Nagaoka assumed that the positive charge is concentrated at a point in the centre of the atom, and the charge is not then uniformly distributed over the sphere. As H. Poincaré expressed the idea: "The neutral atom may be considered to be composed of an immovable principal portion positively charged, round which move, like satellites round a planet, several negative electrons of very inferior mass." Fig. 2 gives but a crude notion of what is meant by concentric rings of corpuscles in rapid orbital motion about a central positively charged sphere.

FIG. 2.—Diagrammatic Representation of one form of the Corpuscular Ring Hypothesis of the Constitution of an Atom.

The atom has thus been compared with the planet Saturn and its rings—the **Saturnian atom**. This intricate mechanism is supposed to represent the inner structure of the chemist's atom. The atoms, in turn, are supposed to be disposed in the molecule in an analogous manner. Consequently, the relation of the electrons to the whole molecule must be somewhat complex. The apparent hardness and impenetrability of the atom, so well emphasized by Isaac Newton, now appears to be a kind of gyrostatic equilibrium due to the rapidity of motion of the component electrons. We are told that a soft wax-candle fired from a gun can be shot through a deal board, and that the speed of the jets of water in hydraulic mining in California was so great that a man could not strike an axe into the water which had just left the nozzle. It is quite possible therefore that an atom may appear to be rigid owing to the rapid motion of the constituent electrons. "Hardness," it is said, "is merely softness in rapid motion."

One reason for postulating the Saturnian atom as a basis for investigation is rather

interesting. J. Plateau⁴ spun little spheres of oil in a mixture of alcohol and water so that they rotated while suspended in the liquid. During their rotation, the little spheres flattened at their poles and bulged at their equators. When the speed of rotation of a sphere was great enough, rings of oil were thrown off. The rings broke and coalesced to form little spherules which rotated on their own axes and revolved round the parent sphere. This remarkable experiment has been used for illustrating a possible mode of formation of a solar system like ours from a contracting spinning nebula. The Saturnian atom is considered to be the figure of equilibrium of a mass of rotating electrons in a sphere of positive electrification. It is not difficult to understand how the "figure of equilibrium" of a rotating fluid cannot be spherical, for gravity is progressively neutralized in passing from the axes of rotation (the poles) towards the equator, where the mass is specifically lighter. The faster the spin the more oblate the spheroid, and in the extreme case, with an increasing speed of gyration, the spheroid must become either a flattened disc, or else, at some critical velocity, there must be an interruption in the process of flattening, and the spheroid must alter fundamentally in shape or break into pieces. H. Poincaré, G. H. Darwin, and J. H. Jeans have investigated the subject mathematically.

E. Rutherford and H. Geiger⁵ found that when the α -particles from a radioactive substance encountered thin gold-leaf, most of the particles pass through with only a slight deflection; but every now and again, about one in 8000, one of these particles recoiled towards its source. The idea is illustrated by Fig. 3, which

FIG. 3.—Paths of a Stream of α -particles in the Vicinity of the Positive Nucleus.

represents diagrammatically the hyperbolic paths of the α -particles in the vicinity of the positive nucleus. The phenomenon, known as the scattering of the α -particles, obeyed the same laws as the repulsion of an electric charge in motion by one at rest. From the amount of scattering, it was concluded that at some point in their paths these particles pass through a very intense electrostatic field caused by a positive charge, whose magnitude is approximately one-half the at. wt. of the metal through which the scattering occurs; and that the α -particle approaches the repelling positive charge within a distance which is infinitesimal as compared with the radius of the atom. The radius of an atom is approximately 10^{-8} cms., consequently, the α -particles must have approached the hydrogen nucleus so closely that their centres were only 1.7×10^{-13} cms. apart. Otherwise expressed, the α -particles penetrated within the atom of gold. Hence, also, E. Rutherford concluded that the positive nucleus is an essential part of the mass of the atom, and has linear dimensions which are exceedingly small in comparison with the linear dimensions of an atom. It is estimated that with hydrogen, the charge on the positive nucleus is 4.7×10^{-10} electrostatic units; the mass is 1.6×10^{-24} grms.; and the radius is 1.0×10^{-16} cms.; or, as P. Zeeman puts it, the diameter of the electron is $\frac{1}{40,000}$ th part of the diameter of an atom; and in the solar system, the diameter of the earth is $\frac{1}{20,000}$ th of the diameter of its orbit round the sun. Hence, if the earth represents an electron, an atom is a sphere having a sun as centre (positive nucleus), and a radius eq. to twice the distance of the earth from the sun.

E. Rutherford, therefore, gave greater precision to the vague entity of positive electricity of J. J. Thomson's atom; he assumed that the atom—the so-called Rutherford atom—contains (i) a nucleus no larger than 10^{-16} cms. in diameter and charged with positive electricity. (ii) A cluster of negative electrons revolving about the central nucleus in orbital motion, each about 10^{-13} cms. in diameter.

(iii) An outer group containing but a few electrons rotating about the inner group and which are much less rigidly attached to the atom. To explain why the physical and chemical properties of the atom do not go hand in hand with X-ray and γ -ray phenomena, it is further assumed that (a) the outer group of electrons are responsible for the physical and chemical properties of the atom—**valency or mobile electrons**; that (b) the inner group determines the phenomena associated with radioactivity; that (c) the positive nucleus mainly determines the mass of the atom, while the masses of the groups of negative electrons are but a small fraction of the at. wt.; that (d) the positive charge is numerically equal to the sum of the negative charges on all the electrons, so that the atom is electrically neutral; and that (e), relative to their size, the electrons are relatively about as far from each other and from the nucleus as the planets are distant from one another and from the sun.

N. Bohr was the first to represent the mechanism of the intra-atomic motion; he applied the quantum theory of radiation to Rutherford's model atom to calculate the size of the atom, and explained the series of lines found in the spectrum of some elements. The various electrodynamic complications which attend the motions of the electrons were disregarded in the first approximation, and the purely electrostatic attraction between the positive nucleus and the negative electron is considered. The motion of the electrons about the nucleus was treated as if the attractive forces followed the inverse square law, and the mass of the nucleus was treated as indefinitely large in comparison with that of the electron. The development of the theory depends on two simple theorems in elementary physics.

If a body, say an electron, of mass, m , is moving uniformly on a circular path of radius, r , with a velocity, V , while under the influence of a central force, the normal component of the force, *i.e.* the centripetal force, F , is given by the relation:

$$F = \frac{mV^2}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and the potential energy of an electron with a charge, e , at a distance, r , from a nucleus of charge, E , is

$$\text{Potential energy} = \frac{eE}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If the electron revolves in its orbit, ω times per second,

$$V = 2\pi\omega r \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and if the force of attraction, F' , between nucleus and electron varies inversely as the square of their distance, r , apart, then, as in the gravitation law:

$$F' = \frac{eE}{r^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

If the system is in equilibrium,

$$F = F'; \text{ or } \frac{mV^2}{r} = \frac{eE}{r^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and, from (2), (3), and (5),

$$\text{Potential energy} = m(2\pi\omega r)^2 = \frac{eE}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

The kinetic energy of the electron is $\frac{1}{2}mV^2$, or, from (3):

$$\text{Kinetic energy} = \frac{1}{2}m(2\pi\omega r)^2 = \frac{1}{2} \cdot \frac{eE}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

In a system consisting of electrons and a positive nucleus, in which the nucleus is at rest, and the electrons move in circular orbits with a velocity small in comparison with that of light, the kinetic energy is numerically equal to half the potential energy (*cf.* 1. 13, 14). The work, W , required to move the electron from its orbit to a position of rest at infinity is the difference between the potential and kinetic energies of (5) and (6), or $\frac{1}{2}eE/r$. Therefore, the potential energy, W , of an electron in its orbit is:

$$W = \frac{eE}{2r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where W may have any value ranging from zero to infinity.

It is here assumed that the mass of the nucleus, M , is very great in comparison with m , the mass of the electron. If the ratio m/M be not negligibly small, m must be replaced by $mM/(M+m)$, and the value of Rydberg's constant is reduced by the factor $M/(M+m)$. For hydrogen $N \times 109,675$ agrees very well with observation, for helium, the corrected value $N' = NM/(M+m)$. A. Fowler found that the hydrogen lines observed by him were not accurately represented by formula (13). N. Bohr, however, showed that this objection does not apply if the mass of the central nucleus be taken into account by making $N' = NM/(M+m)$. This also agrees with the observations of E. J. Evans. The ratio $m/M = 1 : 1836$ very nearly.

The neutral hydrogen atom is assumed to have one electron, Fig. 4, and hence $E=e$. If the atom acquires another electron, as it does in the canal rays, it will be negatively charged, Fig. 5. The relative sizes of the neutral and negatively charged atoms are illustrated by the diagrams, Figs. 4 and 5.

FIG. 4.—Neutral Hydrogen Atom (Diagrammatic).

E. Rutherford proposed to apply the term *proton* to the hydrogen nucleus of mass one, and unit positive charge; O. Masson suggested the term *baron*. O. J. Lodge has suggested a number of terms but preferred *hylon*; A. H. Patterson, *hydron*; F. Soddy said that the term *hydrion* is already in use for the positively charged hydrogen ion. A. H. Compton has also discussed this subject.

Since the configuration with the neutral hydrogen, Fig. 4, has a greater value for W than the configuration with the negatively charged hydrogen atom, Fig. 5, it might

FIG. 5.—Negatively Charged Hydrogen Atom.

be anticipated that a hydrogen atom can under certain conditions acquire a negative charge; but since the energy of a hydrogen atom with two negative charges is very small, a hydrogen atom cannot be expected to acquire two negative charges. If the integral constant, n_2 , in (7) be made unity, and n_1 be assigned integral values greater than n_2 , say, $n=2, 3, 4, \dots$, a series of spectral lines is obtained. These lie in the ultra-violet. This series was not known when N. Bohr published his theory, but has since been discovered by T. Lyman—*Lyman's series*. If n_2 be assigned the value 2, and n_1 be made 3, 4, 5, \dots , the well-known *Balmer's series* (1. 7, 7) is obtained. If n_2 be assigned the value 3, and n_1 be made 4, 5, 6, \dots , *Paschen's series* in the infra-red is obtained. Higher

FIG. 6.—The Series Spectra of Hydrogen.

values of n_2 are too far in the infra-red to be observed. These series are illustrated diagrammatically by Fig. 6. The Balmer series has not been observed in the laboratory beyond the line $n_1=12$, but in stellar spectra, the series has been followed to $n_1=33$. It is assumed that in vacuum tubes, there are no hydrogen atoms of greater diameter than that given by $n_1=12$, where the calculated radius $r=0.8 \times 10^{-6}$ cms., which is equal to the mean distance in the mols. of the gas at

about 7 mm. press.; but for $n_1=33$, the radius is $r=0.6 \times 10^{-5}$ cms., and the press. about 0.02 mm. On this theory, therefore, there may be hydrogen atoms in the stars about a thousand times greater than the size of the normal atom.

The formation of a molecule of hydrogen from two atoms of that element is considered by N. Bohr. The nuclei of two such atoms repel one another. If the electrons of two adjacent atoms are rotating in the same direction, two parallel currents of electricity are in proximity, and therefore attract one another, and arrive in the same plane. The molecule thus consists of the electrons which revolve like the governor-balls of an engine about an axis formed by the two nuclei. He calculated the energy liberated in the process of combination $2H=H_2$ to be 60 Cals. per mol, a result in substantial agreement with the value 76 Cals. per mol, calculated by I. Langmuir from the heat conduction of an incandescent wire in hydrogen. The last-named first gave 130 Cals., but, after N. Bohr's calculation, he revised the calculation and reduced 130 to 76 cals.

According to N. Bohr, the neutral helium atom has two electrons revolving about the nucleus, Fig. 7, so that the nuclear charge is $E=2e$. When from ionization, or other cause, the atom loses one electron, the remaining positively charged atom has one electron, with charge $e=\frac{1}{2}E$, revolving about the nucleus. The spectral lines are accordingly represented by putting $E=2e$, and, from (13), the frequency will be given by $\nu=4N(n_2^2-n_1^2)$. The series with $n_2=1$ and $n_2=2$ are too far in the

FIG. 7.—Neutral Helium Atom.

FIG. 8.—Positively Charged Helium Atom.

ultra-violet to be observed; but the series $n_2=3$ can be divided into two parts according as n_1 is odd or even; and both series have been observed by A. Fowler with mixtures of hydrogen and helium, when the hydrogen seems to be required to ionize the helium. At first the spectrum was attributed to hydrogen, but they are now regarded as being produced by positively charged helium atoms. Similarly, when $n_2=4$, the spectrum consists of two parts, according as n is even or odd. If even, a series analogous to J. J. Balmer's series is obtained, the so-called *W. H. Pickering's series*. The latter series was observed in 1896 in the spectrum of the star ζ -Puppis, and attributed to hydrogen.

N. Bohr applied his theory to the lithium atom on the assumption that the atom has three electrons; the nuclear charge is $E=3e$. This atom should give the spectral series $\nu=9N(n_2^{-2}-n_1^{-2})$, and in the special case for $n_2=2$, in addition to the lines

coinciding with J. J. Balmer's series, J. W. Nicholson observed a pair of series with $n_1^2=(m \pm \frac{1}{3})^2$, in the spectra of the Wolf-Rayet stars.

N. Bohr's theory does not account for the ordinary spectrum of hydrogen or helium. J. W. Nicholson has shown that coplanar, concentric rings of vibrating electrons are unstable when electrostatic forces are alone taken into consideration; but N. Bohr maintains that no such oscillations occur in the plane of the orbit of

FIG. 9.—Neutral Lithium Atom.

the electrons, and the objection does not apply. J. W. Nicholson bases his calculations on an atom of the Rutherford type, but he does not use the quantum hypothesis. The energy which is required to produce the spectrum comes from outside, and is

not, as in N. Bohr's theory, atomic energy. Two elements have been recognized by their spectra, but they have not yet been recognized on earth—*coronium* occurs in the coronal spectrum of the sun; and *nebulium* in the spectra of nebulae. He calculated the possible spectral lines of nebulium, and found that the theory did not account for two of the lines which had been recorded for this element in the spectra of the nebulae. M. Wolf later found that these two lines in the spectrum of the ring nebula in Lyra had a different origin from the true nebulium lines; J. W. Nicholson also predicted the existence of a new nebulium line not previously noticed, which W. H. Wright found on photographic plates taken years previously, but which was so faint that it escaped notice.

Working from an atom of the Rutherford type, J. W. Nicholson (1914) has calculated spectral lines for vibrating electrons in systems with an assumed atomic number $1e$, $2e$, $3e$, $4e$, $5e$, and $6e$, and with the respective at. wt.:

Element . . .	Prh	—	—	Nu	Pf	Arc
At. number . . .	1e	2e	3e	4e	5e	6e
At. wt. . . .	0.082	0.327	0.736	1.31	2.1	2.9

The lines corresponding with $1e$ exist in the spectra of nebulae and have been assumed to belong to an unknown primitive element called *proto-hydrogen*, Prh; the lines corresponding with $2e$ are present in nebulae and in Nova Persei; similarly faint lines corresponding with those computed for $3e$ are found in nebulae; $4e$ belongs to *nebulium*, Nu; the lines for $5e$ have not been found in nebulae, but those in the solar corona have been supposed to represent a non-terrestrial *proto-fluorine*, Pf; the lines for $6e$ exist in the spectra of nebulae and have been supposed to represent an unknown element *arconium*, Arc. Lines corresponding with $7e$ are also found in nebulae.

According to F. A. Lindemann, N. Bohr's is but one of a number of models which can be devised to explain the structure of the atom from the standpoint of mechanics. The possible models may be grouped as static or dynamic. In each case assumptions must be made to assure the stability of the atom. Chemists prefer to consider the valency electrons as fixed on the surface of the atom in certain definite positions; this coincides with numerous observations such as the existence of the asymmetric carbon atom, the phenomena of stereochemical hindrance, etc. If a statical model be assumed, with the valency electrons in definite positions in the atoms, and a central positive nucleus, it is necessary to assume repulsive forces in the atom which act in opposition to the attractive forces between positive and negative charges. Thus, J. J. Thomson said that there is no necessity to assume that the observed laws of electrostatics prevail at very small distances. He postulated that the forces acting on an electron in an atom are (i) a radial repulsive force varying as the cube of the distance from the centre, and diffused uniformly through the whole atom; and (ii) a radial attractive force varying inversely as the square of the distance from the centre, and confined to a limited number of radial tubes of force in the atom. By this means he is able to explain the relation between the velocity of emission of the electrons and the incident frequency; and to explain Balmer's series. W. Peddie also explained the variation in the properties of atoms and molecules as due to structural conditions within the atom, and to the presence of regions of attractive force alternating with regions of repulsive force. J. J. Thomson favoured a statical theory; he said in respect to N. Bohr's theory:

It seems hardly likely that much progress can be made in the soln. of the difficult problems relating to chemical combination by assigning in advance definite laws of force between the positive and negative constituents of an atom, and then on the basis of these laws building up mechanical models of the atom. We must first of all, from a study of chemical phenomena, learn the structure and arrangement of the atoms, and if we find it necessary to alter the law of force acting between charged particles at small distances, even to the extent of changing the sign of that force, it will not be the first time in the history of science that an increase in the range of observational material has required a modification of generalizations based upon a smaller field of observations. Indeed in the present

case, entirely aside from any chemical reasons, a study of the mathematical theory of the electrons leads, I believe, irresistibly to the conclusion that Coulomb's law of inverse squares must fail at small distances.

In the dynamical models, favoured by N. Bohr, J. W. Nicholson, etc., the chemical facts are not so much emphasized, the repulsive force is replaced by a centrifugal force, and it is assumed that the electrons in rotation do not radiate energy. The mathematical treatment is largely concerned in finding whether an assumed configuration of electrons and nucleus will be stable mechanically; the chemical properties appear to be of secondary importance. The case for the ring electron has been summarized by H. S. Allen; on the physical side it has been adapted to explain: (i) the loss of energy by radiation; (ii) diamagnetism and paramagnetism; (iii) the asymmetry of certain types of radiation; (iv) the absorption of X-rays by magnetic substances; (v) the ionization of gases by X-rays; (vi) thermoelectric effects; (vii) the radiation formula of M. Planck; (viii) series lines on spectra; (ix) the Zeeman effect; (x) the Stark effect; (xi) solar electron streams and auroræ; (xii) cohesion; etc.

The periodic law.— Ever since J. B. A. Dumas (1851) wrote :

Every chemical compound forms a complete whole. Its chemical nature depends primarily on the arrangement and number of the constituent atoms, and to a less degree on their chemical nature,

it has been considered a fundamental principle in chemistry that substances similarly constituted have similar properties. If stable aggregates of electrons are similarly constituted, the properties of the resulting atoms, within certain limitations, will be similar even though the at. wt. be different. In W. Kossel's modification of J. J. Thomson's ring system, the two- and eight-ring systems are assumed to be the most stable, and while the outer ring of electrons determines the valency of the atom, the inner stable rings determine the characteristic properties of the element. The first series in the periodic table has an inner ring with two electrons and an outer ring with from zero to seven electrons, the addition of one more electron to the outer ring makes a stable ring from which no more electrons can escape :

First series	(2)	(2)1	(2)2	(2)3	(2)4	(2)5	(2)6	(2)7
Second series	(2,8)	(2,8)1	(2,8)2	(2,8)3	(2,8)4	(2,8)5	(2,8)6	(2,8)7
Third series	(2,8,8)	(2,8,8)1	(2,8,8)2	(2,8,8)3	(2,8,8)4	(2,8,8)5	(2,8,8)6	(2,8,8)7

Hence, when the elements are arranged in the order of increasing mass, there is a certain similarity in the grouping at certain intervals. Thus, the properties connected with a two-ring group can only recur at intervals; similarly with more complete systems. Consequently, we can divide the various groups of electrons into families such that any one family is derived from the preceding members by the addition of another ring of eight electrons. This idea gives a rather definite conception of the meaning of the periodic law. A periodic law thus appears as a necessary consequence of the hypothesis that atoms are built of stable systems of concentric rings of electrons; for obviously, without specifying particular numbers, *certain rings of electrons recur periodically with an increase in the number of electrons which make up the atom*, and atoms with related rings must possess many common properties in virtue of the similarity in the grouping of some of the rings. Thus, J. J. Thomson has demonstrated that the spectra of such groups would be in many ways similar.

It is even possible to see how elements with similar properties may fall into the "wrong" group in Mendeléeff's table if classed solely by their at. wt. Starting from sodium in the periodic table, it follows that if the atoms of the elements are really aggregates of electrons, the sodium atom might collect more electrons until, say, two different stable systems capable of separate existence are formed. Thus, sodium might furnish two subgroups—potassium and copper. The properties of an element are supposed to be determined by the structure of rings of electrons,

and differences in the properties of members of the subgroups is due to the differences in the internal structure of the atoms although the atoms probably possess some rings in common. Each subgroup, by a further condensation of electrons, forms the succeeding family members indicated in the vertical columns of the table. Consequently, it is quite true, in a general way, to say that the elements were evolved in the order of their at. wt., but they must also have evolved in groups down the vertical as well as along the horizontal lines of Mendeléeff's table. Hence, as J. N. Lockyer observed, the elements do not always appear in the cooling stars in the order of their at. wt. In virtue of this **multiple growth hypothesis** of A. C. and A. E. Jessup, it is to be expected that in some cases an element in any particular group may contain more or less electrons, and hence have a slightly greater or less at. wt. than adjacent elements in the next succeeding group.

Again, since the nuclear charge of an atom of any element corresponds to the position of the element in the series of increasing at. wt., and since the physical and chemical properties of an element depend on the magnitude of this nuclear number; and since any given number of electrons may conceivably assume different stable configurations, it is possible for two or more elements to have the same nuclear charge, and to occupy the same place in the periodic table. These are the isotopes or isotopic elements of F. Soddy and co-workers.

The mechanism of multi-electronic systems has not been followed so far as in the simple case of hydrogen. It is, however, assumed that the electrons are arranged in rings about the nucleus, but the number and orientation of the rings is unknown. In the absence of more definite information, the *periodic law* is taken to indicate that the disposition of the electronic rings, with elements of low at. wt. arranged according to their atomic number, is such that, with a periodicity of 8, every 9th element is similar to the first. This is illustrated in Table III. Again, the valency of a series of eight elements rises from zero to four, and then decreases back to zero. The valency of an element is taken to be fixed by the number of electrons in the outermost ring, and it is through the agency of these electrons that one atom is coupled to another. With elements of low at. wt., the number of electrons in the outermost ring will be odd or even according as the total number of electrons in the atom is odd or even. This means that the valency of an element of low at. wt. is odd or even according as the at. number of the element in the periodic series is odd or even. The binding of the outer electrons in any horizontal series will become weaker with increasing electrons per atom. This corresponds with the observed increase in the electropositive character of an element for an increase of at. wt. in any group of the periodic system. At. vols. are usually deduced from measurements on molecules *en masse*, and it is observed that the elements in the same column of the periodic system have approximately the same at. vol., while the volume changes from column to column and is greatest for columns corresponding with the smallest valency and smallest for elements with a valency of 4. The number of electrons in an atom is taken to be fixed by the at. number of the element. Both A. van den Broek, and N. Bohr state that the at. number is equal to the number of positive charges on the nucleus such that the positive charges are numerically equal to N_e . J. Chadwick found that when measured at any point between 3×10^{-12} and 10^{-10} cms. from the nucleus, the nuclear charge is equal to the at. number; and the law of force is that of the inverse square. It is also inferred that there are no electrons between the nucleus and the ring *K*-radiation electrons. F. Sanford calculated the magnitude for the central positive charge of an atom from the equation for the orbital motion and the equation $\frac{1}{2}MV^2 = h\nu$; but the latter requires h replacing by a function of mass, m . C. G. Barkla regarded the charge on the nucleus to be $\frac{1}{2}Ae$, where A is the at. wt. of the element. The first two electrons are taken to be arranged in a single ring; and the next two electrons in another ring. A ring with four electrons will have a smaller value for the total energy than two rings with two electrons in each. It is assumed that a ring with four electrons will not occur before boron, at. number 5, or carbon, at. number 6, on account of the observed ter-

or quadri-valency of these elements. The periodic system suggests that in neon, at. number 10, a ring of eight electrons occurs; and unless the at. number is greater than 13, the configuration with two rings each with four electrons will correspond to a smaller value for the total energy than a configuration of one ring with eight electrons. N. Bohr's arrangement of the electrons in the atoms of elements of low at. wt.—from hydrogen to chromium—is shown in Table III. The iron-group occurs

TABLE III.—N. BOHR'S ARRANGEMENT OF ELECTRONS IN THE ATOMS OF ELEMENTS OF LOW ATOMIC WEIGHT.

Atomic number.	Element.	1st ring.	2nd ring.	3rd ring.	4th ring.	5th ring.
1	Hydrogen . .	1	—	—	—	—
2	Helium . .	2	—	—	—	—
3	Lithium . .	2	1	—	—	—
4	Beryllium . .	2	2	—	—	—
5	Boron . .	2	3	—	—	—
6	Carbon . .	2	4	—	—	—
7	Nitrogen . .	4	3	—	—	—
8	Oxygen . .	4	2	2	—	—
9	Fluorine . .	4	4	1	—	—
10	Neon . .	8	2	—	—	—
11	Sodium . .	8	2	1	—	—
12	Magnesium . .	8	2	2	—	—
13	Aluminium . .	8	2	3	—	—
14	Silicon . .	8	2	4	—	—
15	Phosphorus . .	8	4	3	—	—
16	Sulphur . .	8	4	2	2	—
17	Chlorine . .	8	4	4	1	—
18	Argon . .	8	8	2	—	—
19	Potassium . .	8	8	2	1	—
20	Calcium . .	8	8	2	2	—
21	Scandium . .	8	8	2	3	—
22	Titanium . .	8	8	2	4	—
23	Vanadium . .	8	8	4	3	—
24	Chromium . .	8	8	4	2	2

at the end of the third period of eight elements. Here the elements of neighbouring groups show similar chemical properties, indicating that the configurations of the electrons in the elements of this group differ only in the arrangement of the inner electrons. After the iron group, the period is no longer 8 but 18, suggesting that the elements of higher at. wt. have a recurrent configuration of 18 electrons in the innermost ring. Such a ring would probably be unstable, and the electrons may be arranged in two parallel rings. The presence of the rare earth group indicates that an alteration of the innermost rings occurs.

In the case of **multivalent elements**, it is possible that electrons can move from the outer to an inner ring, so that multivalency corresponds with a kind of infratomic tautomerism. Thus, with univalent copper, the arrangement for the atoms would be 2, 8, 8, 10, 1, while with bivalent copper the arrangement may be 2, 8, 8, 9, 2.

Line spectra.—If through some agency like electronic bombardment, one or more electrons in the ring *B* of a neutral atom of, say, calcium, Fig. 10, be made to revolve in the ring *C*, the displaced electron would not radiate while moving in the orbit *C*, but it would send out a radiation of a single definite wave-length in passing back from *C* to the stable orbit *B*. If the disturbance cause one or more electrons in orbit *B* to revolve in orbit *D*, then as the electrons dropped back either directly to orbit *B*, or to orbit *C* first and then to *B*, the atoms in returning to the neutral

state might emit a radiation of two or possibly three definite and determinate wavelengths. Atoms may thus emit a 1, 2, 3, . . . line spectrum according to the violence of the shock to which they are subjected.

Single line spectra are attributed to oscillations produced by the return to their orbits of electrons which have been displaced by some external influence. J. C. McLennan and J. P. Henderson found that the vapours of cadmium, zinc, and mercury emit single line spectra when traversed by electrons possessing the proper amount of energy. Spectra with lines are obtained with voltages 15.3, 11.85, and 12.5 respectively; below the voltages there is a definite range for each metal in which the characteristic single line spectra alone can be excited. In the simple case, the single line spectrum may be produced by the return of the electron, and in the case of spectra with many lines, by the return of a complete ring of electrons to their original positions about the central nucleus. J. C. McLennan also obtained similar results with magnesium. J. C. McLennan and J. P. Henderson obtained the following potentials in volts representing the work required to remove an electron from a neutral molecule:

Mg	Zn	Cd	Ca	Sr	Ba	Li	Na	K	Rb	Cs
4.28	4.04	3.81	2.94	2.69	2.24	1.85	2.11	1.61	1.56	1.39

J. Franck and H. Hertz obtained 4.9 volts for the ionizing potential of mercury, and with electrons of such a voltage, mercury vapour emits a single line spectrum $\lambda=2537$. This amount of energy corresponds very nearly with a quantum of energy $h\nu$, where ν is the frequency of the observed spectrum line. If e denotes the charge in the electron, the relation between volts, V , and frequency ν is $Ve=h\nu$. The order in the above table agrees with the known electropositive characters of the different elements. It also shows that some atoms have a greater affinity for electrons than others; the atoms with the lowest electron affinity belong to the elements characterized as electropositive.

W. Kossel assumes that the K -radiation occurs when an electron jumps from the third ring to take the place of one removed from the first or innermost ring, L -radiation corresponds with the removal of an electron from the second ring, and M -radiation, with the removal of an electron from the third ring. W. Kossel then infers that there are as many lines in these high-frequency spectra as there are rings in the atom; and the frequencies of the different lines are related as

$$\nu_{K\beta} - \nu_{K\alpha} = \nu_{L\alpha}; \text{ and } \nu_{K\gamma} - \nu_{K\beta} = \nu_{L\beta} - \nu_{L\alpha} = \nu_{M\alpha}$$

where the subscripts refer to the lines in each series. He showed that these relations are satisfied by the elements ranging from calcium to zinc. I. Malmer also found the K_{α} - and K_{β} -lines of some elements of higher at. wt. are in accord with W. Kossel's rules.

The absorption spectrum of a gas can be readily interpreted on N. Bohr's theory, for if in an inert gas the majority of the atoms are in the state $n=1$, and radiation passes through the gas in complete quanta, a quantum can be absorbed only if it is adequate to move an electron from one orbit to another, or to set the electron free altogether. Thus the absorption spectrum will consist of the series $n_2=1$ together with a continuous absorption band running upwards from the head of this series, where $n_1=\infty$. The range covered by this band is the range for which the photoelectric effect occurs, and the presence of this absorption band is evidence of the occurrence of photoelectric action. According to R. W. Wood, the absorption spectrum of sodium vapour is of this type. Fifty lines were observed in the absorption spectrum, and their position agreed with those of the principal sodium series, and in

FIG. 10.—Electrons in Bohr's Atoms of Calcium.

addition, there was a continuous absorption band beginning at the head of this series, and extending to the ultra-violet.

According to N. Bohr, the hydrogen atomic system with a circular orbit has one degree of freedom, but A. Sommerfeld showed that more probably the atomic system has two degrees of freedom, and that the electrons may move in elliptical orbits of every eccentricity in one place. A. Sommerfeld's calculations also show that a single line in the spectrum does not correspond necessarily with the passage from one possible state to another possible state, but rather from one group of possible states to another group of such states. He thus extended N. Bohr's theory to explain the fine structure of hydrogen and similar series lines, and the X-ray spectra. Some spectral lines, even in the absence of magnetic or electric fields, are not strictly single, but have a number of satellites. It may be that this separation is due to some perturbation which distorts the elliptical orbits making the energies of ellipses of different eccentricities not the same. A. Sommerfeld says there is no perturbation; he has shown that it has been assumed that the mass, m , of the particles is independent of their velocity; and in place of m he substitutes H. G. Lorentz's expression, $m = m_0(1 - \beta^2)^{-\frac{1}{2}}$ —*vide supra*—and obtained some results which agree with observation.

The subject has been further discussed by M. Siegbahn, P. Ehrenfest, L. Föpl, T. Rella, O. Hinsberg, F. Reiche, A. Rubinowicz, S. R. Milner, E. Gehrcke, F. Kirchhoff, R. T. Birge, T. Terada, J. Larmor, H. S. Allen, O. Chwolson, E. C. Kemble, L. Vegard, M. Brillouin, R. Ladenburg, A. Smekal, J. Franck and F. Reiche, J. Franck and W. Grotrian, J. Stark, E. O. Hulburt, W. H. Westphal, A. Szarvassi, H. T. Wolff, A. Landé, P. Debye, R. Glocker and M. Kaupp, J. Kroo, F. Wenzel, E. Kohlweiler, A. Berthoud, K. Fehrlé, J. Chadwick, R. Ladenburg, G. A. Schott, N. Nordström, G. Laski, G. Kirsch, F. J. Wisniewsky, W. D. Harkins, S. H. C. Briggs, F. A. Henglein, A. E. Lacomblé, S. N. Basu, K. Fösterling, H. Teudt, J. Marshall, M. and L. de Broglie, A. Korn, W. Schottky, J. M. Burgers, W. Kossel, G. H. Darwin, A. C. Crehore, O. J. Lodge, H. A. Wilson, W. Daune, W. Heisenberg, A. D. Fokker, M. C. Neuburger, H. S. King, M. Yamada, L. Meitner, M. Brillouin, W. M. Hicks, J. C. McLennan and P. Lowe, O. Oldenberg, E. T. Whittaker, J. A. Ewing, W. Peddie, R. A. Houstoun, J. Duclaux, J. S. Townsend and V. A. Bailey, etc. L. Silberstein applied the theory to atomic systems containing a complex nucleus. A. Smekal discussed the action of the electronic rings in the atom; P. Ehrenfest and N. Bohr, the spectral lines of isotopes.

W. D. Harkins and E. D. Wilson showed that the at. wt. of the elements with low at. wt., beginning with helium, are not multiples of the at. wt. of hydrogen by a whole number; but the multiple differs from a whole number by a nearly constant percentage difference—average -0.77 per cent. They call this the *packing effect*, and regard it as the percentage decrease of mass when hydrogen atoms are aggregated to form more complex atoms. They also developed a scheme of which the atoms of the elements could be regarded as complexes of hydrogen or helium nuclei.

Null-valency.—As just indicated in W. Kossel's ring system, modified from that of J. J. Thomson, it is assumed that the two- and eight-ring systems are the most stable. Such rings are not readily broken down. If an electron escapes from such a system, the positively charged residue will attract surrounding electrons, so that one will immediately dart back to it, and reform the original system. The system so formed will break up as before, and the same cycle of changes would be repeated over and over again. Hence the system will not remain permanently charged; directly it loses an electron another takes its place. Such an atom will be unable to retain a positive or negative charge permanently; and it will not be able to enter into chemical combination. Consequently, it will behave like the members of the group of inert gases.

Electronegative and electropositive characters.—The majority of those working on the structure of the atom believe that the outer ring of the electrons determines the periodicity and valency of the atoms of the elements. C. A. Kraus argues as follows: The outer electrons are held loosely and are able to move from atom to atom. These electrons are very sensitive to changes in condition, such as temp., press., the presence of other atoms, etc. So weak is the bond connecting the electron to an atom, that more electronegative atoms may remove it from the

original atom in question. *The less tendency the metal has to retain its electron, the more electropositive it becomes, and the more readily does it in general react chemically.* Ordinarily, the positive and negative constituents of a compound are held together through the medium of the electron. Under certain conditions, however, the electrostatic force acting between the metallic atom and its electron becomes weakened to such an extent that the negative constituent escapes, carrying the electron with it. The same result may be obtained at high temp. with the fused salt or even with the solid compound. That is when sodium and chlorine combine, the sodium atom gives up an electron to the atom of chlorine, and the atoms are thus held together by the electrostatic forces between the positively charged residue of the sodium atom and the negatively charged atom of chlorine. In a soln. of high dielectric constant such as water, these electrostatic forces are weakened to such an extent that **ionization** occurs resulting in the formation of Na^+ and Cl^- ions. Naturally the properties of those ions are radically different from those of metallic Na and gaseous Cl_2 as we know them. Consider the properties of the systems with a 2-electron ring on the inside, supposed, in W. Kossel's system, to be

Li	Be	B	C	N	O	F
(2)1	(2)2	(2)3	(2)4	(2)5	(2)6	(2)7

When the first member with three electrons is subjected to a small disturbance, an electron is detached from the outer ring. When one electron is lost, the residue has a positive charge, and behaves like a positively charged ion, that is like an electropositive or basic element. The system with four electrons is more stable than the one with three, and it will not be so readily broken as the preceding. This means that this system will not be so basic as the preceding. Similarly the system with five electrons will be less basic than the one with four; and six will be less basic again than five. In the six-electron system the stability is so great that there is little danger of losing electrons from the outer ring, and an electron could lie on the surface of the system without breaking a ring. In that case, the system would receive a negative charge and behave like an electronegative or acidic element. Hence, **the electronegative elements may be regarded as possessing neutral atoms with a tendency to absorb negative electrons from without, and electropositive elements are regarded as neutral atoms with a tendency to part with negative electrons.** The electronegative character increases with increasing at. wt. until the system with nine electrons is reached. This corresponds with the fact that in Mendeléeff's list of elements the electronegative property is practically zero at the end with the alkali metals, and gradually becomes more marked with increasing at. wt. until, at the halogen end, it attains its maximum value. The system with ten electrons resembles the one with three in respect to stability, etc., and the system with eleven resembles the one with four, and so on. The system of three electrons will be most electropositive of the series, with two electrons in the inner ring. It can lose but one electron because, if it lost two, the residue with one electron would immediately attract an electron. Hence, the three-electron system can lose one electron and form a system carrying unit charge of positive electricity. This means that such a system is univalent. The four-electron system would not be so ready to part with electrons as the three-electron system, but it could afford to lose two electrons since it is not reduced to the unstable one-electron group until it has lost three electrons. The group with four-electrons must therefore be bivalent. Against this, however, it must be remembered that positive ray analysis shows that there is no relation between the number of electrons an atom can lose and the valency of the element; thus the inert gas helium readily loses two electrons; the argon atom can carry one, two, or three positive charges; krypton, four; etc.

Chemical combination.—Suppose that we have an atom of the type (2,8)1, and one of the type (2,8)7; the former would be illustrated by an atom of sodium, and the latter by an atom of chlorine: the former can *lose* one negative electron, and the latter can *gain* one, but not more than one. The electrons which escape

from the sodium atom can find a home on the chlorine atom, and if an eq. number of both be present, each of the sodium atoms will acquire a positive charge, and each of the chlorine atoms a negative charge. The oppositely electrified atoms will attract one another, and form a compound NaCl. When electropositive and electronegative atoms are brought into proximity, the former loses and the latter gains an electron, as a result, the former acquires a positive and the latter a negative charge; and the force of chemical affinity is the attraction exerted by the electropositive atom for the electron it has lost to the electronegative atom. Similarly, if eq. quantities of atoms of the type (2,8)2 and (2,8)7 were to be mixed together, and this would be illustrated by magnesium and chlorine atoms, the atoms of magnesium would each lose two negative charges, and each of the chlorine atoms would gain one negative charge. Thus a neutral system would be formed by the combination of two chlorine atoms with one magnesium atom, and MgCl_2 would result. Hence, says J. J. Thomson, from this point of view a univalent electropositive atom is one which can lose one and only one electron to form a stable system under conditions which prevail when chemical combination is taking place. Similarly, *mutatis mutandis*, with univalent electronegative atoms, bivalent atoms, etc. Thus, the affinity of an atom depends upon the ease with which an electron can escape from or be received by the atom. This may be influenced by the conditions prevailing at the time chemical combination is taking place. If the atoms be diffused in a good conducting medium it would be easier for a liberated electron to resist being pulled back to the original atom than if the atoms were diffused in a non-conducting medium. Hence, the valency of an atom may be influenced by the physical conditions under which it is placed. The ability of an atom to enter into chemical combination depends upon its power of acquiring a charge of electricity. Thus chemical affinity is electrical affinity, or, as H. Davy expressed it in 1810, "electrical and chemical attractions are produced by the same cause acting in one case on particles, and in the other on masses."

Abegg's normal and contra-valencies.—We have just seen that the (2,8)1-system can acquire one and only one positive charge by the loss of one negative electron; but it is conceivable that additional negative electrons could be forced into the system so that the total number of electrons increase to (2,8)2, (2,8)3, (2,8)4, . . . (2,8)7; and at the same time the systems would become more and more stable. If an additional electron were forced into the (2,8)7-system, a system with (2,8)8 electrons would be formed. Consequently, (2,8)7 is the greatest number of negative electrons which we can hope to force into the (2,8)-system to furnish a stable system with an electronegative valency of 7—the electropositive valency of the (2,8)1-system is one. Similarly, *mutatis mutandis*, with the other systems, and the properties of the systems containing (2,8)1 to (2,8)7 electrons can be tabulated as follows:

Number of electrons .	(2,8)	(2,8)1	(2,8)2	(2,8)3	(2,8)4	(2,8)5	(2,8)6	(2,8)7	(2,8)8
Valency	{ +0	+1	+2	+3	+4	-3	-2	-1	-0
	-8	-7	-6	-5	-4	+5	+6	+7	+8
	Electropositive.					Electronegative.			

This sequence of properties imitates that observed with the elements:

The first and last members of the series only are null-valent; the second set is univalent electropositive, and the last but one univalent electronegative; the third is bivalent electropositive, and the last but two bivalent electronegative, etc.

This recalls an observation of D. I. Mendeléeff to the effect that the sum of the maximum oxygen and hydrogen valencies of the elements in certain groups of the periodic series is equal to 8; e.g.,

In ignorance of the number of electrons in successive rings, it is inferred that the number of mobile electrons in the outer ring cannot exceed eight, and this represents the greatest charge which has yet been observed, the minimum is zero. It is further assumed that there is a tendency for these electrons in every atom to assume either the maximum or the minimum value. Thus, if an atom has five mobile electrons, it can either lose all five and acquire a positive valency of five, or it can attract three more electrons from without, make its complement up to eight, and thus acquire a negative valency of three. Which of these two possible effects will take place, will depend upon the nature of the neighbouring atom. Thus, if a phosphorus atom be surrounded by hydrogen atoms, under the right conditions of temp., etc., its behaviour would correspond with its gaining three electrons, becoming electronegative, and forming PH_3 with a maximum valency of three; on the other hand, if it be in contact with a strongly electronegative element like chlorine, it appears to lose five electrons, become electropositive, and to form PCl_3 or PCl_5 with a maximum valency of five. Variable valency here meets a rational interpretation, for the whole of the available electrons need not be always removed together. The work done in removing a second electron must be greater than is involved in removing the first. So with phosphorus, the force exerted by the electronegative chlorine atom may suffice to drag three electrons from the phosphorus atom, but only when the conditions are favourable is it possible to drag off another two. This does not explain the rarity of intermediate valencies between three and five.

P. P. von Weimarn assumed that all atoms have a minimum valency of six. From purely chemical considerations R. Abegg and co-workers were led to assume that every element possesses a maximum valency of 8 made up of positive and negative components according as the element is acting as an electropositive or electronegative constituent of a compound. The two valencies of opposite polarity are called **normal valencies** and **contra-valencies**. The normal valencies are supposed to be the stronger, and correspond with the usually accepted maximum valencies of the elements. In the case of the metals the normal valencies are positive and the contra-valencies negative; while in the case of the non-metals, the normal valencies are negative and the contra-valencies positive. Thus:

	Na	Mg	Al	Si	P	S	Cl
Normal valencies	+1	+2	+3	+4	-3	-2	-1
Contra-valencies	-7	-6	-5	-4	+5	+6	+7

Thus, chlorine is univalent in HCl where it is combined with electropositive hydrogen; but it has its maximum heptavalency when united with electronegative oxygen in chlorine heptoxide. A. Werner has also shown how elements have a different valency according as they are united with electropositive or electronegative elements. The relative strengths of the two kinds of valency depend upon the nature of the associated atoms. The alkali metals are so strongly electropositive that they show little if any sign of an electronegative valency; and fluorine appears to be too strongly electronegative to show a positive valency, for it forms no compound with oxygen. When the conditions are such that the latent contra-valencies become operative, complex compounds may be formed.

The fact that in a given family the elements with the greatest at. vol. are usually most electropositive and least electronegative, is taken to mean that when two atoms of different sizes are in contact, the attraction of the smaller atom for the electrons in the larger atom is greater than the attraction of the larger atom for the electrons in the smaller, so that the resultant force will drag electrons from the larger to the smaller atom. Again, since the at. vol. increases with the at. wt., the electropositive character of the elements in a given family increases with the at. wt.

Radioactivity.—According to J. J. Thomson's hypothesis, atoms are built of systems of rotating rings of electrons. The configuration of a system of rotating rings of electrons is dependent not only upon the number, but also upon the energy of the speed of rotation of the rings. Four electrons, for instance, may arrange

themselves at the corners of a square or a tetrahedron. If a four-square system of electrons be rotating faster than a certain critical value, they will be stable; but if their velocity falls below the critical value, the arrangement will become unstable, and the electrons will suddenly arrange themselves in the form of a tetrahedron. Similarly, if a spinning top be rotating faster than its critical value, it will remain stable in a vertical position, but if the speed of rotation falls below this value, the top becomes unstable, and falls down; in doing so, it gives up a considerable amount of energy. These analogies can be extended to complex groups of electrons, say an atom of uranium. Owing to the radiation of energy, the kinetic energy of the electrons is gradually reduced, and the velocity of the spinning rings of electrons can be assumed to be slowly diminishing. When the velocity approaches the critical value, the configuration of the system may be modified, and this is accompanied by an increase in the rate at which kinetic energy is lost by the radiation. When the velocity reaches the critical value, the configuration becomes unstable, an **atomic cataclysm**, or an atomic explosion occurs, and a number of electrons are detached from the original assemblage. In other words, the atom disintegrates and a part of the atom is shot off to form two or more groups of electrons. This also corresponds with the emission of α -particles and emanation from radium. As G. H. Darwin expressed it, the laws of electricity in motion prove that a community of electrons, as pictured by J. J. Thomson, must be radiating or losing energy, and therefore the time must come when it will be run down as a clock does. The aggregate will then spontaneously change into another system (or element) which needs less energy than was required in the former state. If the atoms of the emanation are built of electrons of the same type as the original atom, the process may be repeated with the sub-atoms, and so produce a series of degradation products with a long or a short life. This shows that with atoms of a special kind—*e.g.* high at. wt.—the gradual reduction of the kinetic energy of the electronic motion might produce instability within the atom. The rate of decrease of the kinetic energy may take thousands of years before it reaches its critical value, or it may take place in a very short time. The atoms of the several elements thus represent different aggregates of electrons which have proved by their stability to be successful in the struggle of the elements for a separate existence; just as Heracleitus and Empedocles both argued that forms unsuited to their conditions must perish, while forms suited to their conditions are maintained.

A. Debierne expresses this another way. The fact that radioactive elements emit both α -particles and electrons, may be taken to show that the nucleus itself must be a complex aggregate of positively and negatively charged particles. According to the disintegration theory, an atom of uranium must emit eight α -particles before it becomes a relatively stable atom of lead. The eight positively charged particles are assumed to have come from the nucleus of uranium. The forces, which can hold eight helium atoms, or α -particles, in a volume which is small in comparison with that of the uranium atom itself, must be very different from those which are at present known. The law which determines the time at which the atomic cataclysm with the emission of α -particles shall occur is not known. A. Debierne assumed that the component parts of the complex nucleus are in a state of constant agitation like the molecules of a gas, and, following the laws of probability, when one of the constituents of the nucleus acquires enough kinetic energy it is carried beyond the confines of the nucleus and the atom. L. Meitner has discussed the mechanism of radioactive disintegration and atomic structure.

An enthusiastic writer declares that "the corpuscular theory of J. J. Thomson has enabled chemists to explain the periodic law, valency, chemical action, etc., in terms of known facts." We are also told that more is known about the atom than about matter *en masse*. These statements are surely based on superficial views which are the result of confusing fact and fancy. The electronic model atom has but a remote analogy with the real atom. Analogy may be an invaluable aid to description, but it cannot *prove* a single fact; *omne simile claudicat*—every

analogy limps. J. J. Thomson quite recognized the inadequacy of his model atom, for he pointed out that the number of electrons corresponding with a particular property will doubtless be different if the electrons are distributed in three-dimensional space instead of in coplanar concentric rings; but since similar properties are associated with rings as with shells, it is probable that a system of concentric shells will present somewhat analogous properties. A more complex disposition of the electrons will obtain if the positive electrification be not uniformly distributed in the sphere. Hence, with all their imperfections, these hypotheses throw a most interesting light on Mendeléeff's series and on the possible nature of an atom; though matter still remains an inscrutable and impenetrable mystery—and we are still puzzled, for, as W. Crookes has said: "The list of elements extends before us as stretched the wide Atlantic before the gaze of Columbus, mocking, taunting, and murmuring strange riddles which no man has yet been able to solve." Each forward step in our knowledge carries us backwards to a vaguer and remoter past.

§ 4. Electronic Hypotheses of Chemical Combination and Valency

Truth is the daughter of time.—FRANCIS BACON.

In recent years there has been a constantly growing tendency to apply the electronic theory to explain chemical phenomena. It is assumed that electricity has an atomic structure, and is not continuous; and that positive and negative units of electricity are associated as constituent parts of the chemical atom. Consequently, the association of atoms to form molecules involves an investigation of the structure of fields of force exerted on the outer surface of the atom. The different hypotheses usually take one of two forms:

1. Every chemical bond between two atoms involves a *transfer* of one negative electron from one atom to the other, so that the one atom is charged positively and the other negatively.

2. If the electrons are actually displaced, J. Stark¹ considers that some phenomenon resembling the selective absorption of light takes place, and that when the electrons return to the atom, a phenomenon resembling fluorescent radiation occurs.

As previously indicated, the atom can be regarded as constituted of a positive nucleus, with n electrons rotating in orbits about a central nucleus—*dynamical hypotheses*; or, the electrons may be confined to particular parts of the structure—*statical hypotheses*. Physicists have a predilection for the former, chemists for the latter. J. Larmor, for example, compared the atom with a clock, the outer electronic shell being the pendulum, maintained in continuous vibration by the energy of the core imparted through an unknown escapement mechanism which parcels out quanta of energy.

In illustration of the dynamical hypotheses, W. Kossel based a theory of chemical combination on N. Bohr's atom model, and on R. Abegg's theory of contravalencies—*vide*

FIG. 11.—W. Kossel's Atomic and Molecular Models.

1. 5, 14. He distinguishes between outer or valency electrons, and inner electrons, and assumes that the number of electrons in the outer ring varies periodically from one to eight. He regards a ring of eight or two electrons as being exceedingly stable. His view of the structure of the argon atom, and of the molecules of hydrogen chloride and calcium oxide are represented diagrammatically in Fig. 11. The eight electrons are assumed to be constantly rotating in their orbit. In discussing the formation of complex salts like potassium chloroplatinate, K_2PtCl_6 , he shows that in platinum tetrachloride, PtCl_4 , platinum shows a normal positive valency of 4, but owing to its contravalencies, it can take up two more electrons from the potassium atom and thereby take up two more chlorine atoms. F. Kirchhoff modified W. Kossel's ideas a little, and represented, by Fig. 12, the union of an atom of oxygen—having two electrons on the inner and six in the outer ring—with two atoms of hydrogen with a single electron. M. Remy extended the theory of the formation of polar compounds to all chemical compounds.

FIG. 12.—Molecule of Water, H_2O .

W. Kossel continued: When a multi-charged central atom like Pt^{++} is attached

to a negative charge, work is gained; the amount of this energy decreases as the number already attached increases, for the attraction of the central positively charged atom for the electronegative atoms is more and more compensated by the repulsion of those which are already attached; finally, a limit is reached when external work has to be done in order to force another negatively charged atom into the ring. By making certain assumptions as to the relative sizes of the atoms, he calculates the work, W , gained when negatively charged atoms are attached one by one from a ring round a positively charged atom. The work gained is

FIG. 13.—Work required to form complex Salts with an increasing Number of Negatively Charged Atoms, and an increasing Number of Nuclear Positive Charges.

plotted in Fig. 13, as ordinate against n , the number of negatively charged atoms, for different values of the positive charge E on the central atom. The maximum value of W shifts more and more towards larger values of n as E is increased. This means that the tendency to form complex salts increases with the increasing positive valency or charge of the central nucleus. In illustration, magnesium has two normal positive valencies, $E=2$; the curve shows that the maximum number of chlorine atoms it can attach is between three and four; and it does form the complex salt KMgCl_3 . Similarly for antimony, $E=5$, the maximum is near six, and it forms the complex KSbCl_6 ; likewise for platinum with Pt^{++} , $E=4$; n is between five and six; and it forms the complex K_2PtCl_6 ; while Pt^{++} , $E=2$; n is between three and four; and it forms K_2PtCl_4 . The agreement is not in all cases so satisfactory as this. I. Traube has discussed this subject.

N. Bohr also showed that the work required to remove an electron from the outer ring decreases with an increase in the number of electrons in the inner ring, so that the electropositive character of the elements in a given family group should increase with the at. number. This is in accord with facts. Cæsium is the most electropositive element in the alkali family. Iodine is less electronegative than any member of the halogen family; as is illustrated by the deposition of iodine on the cathode during the electrolysis of iodine monochloride. The ease with which the members of the argon family are ionized illustrates the same thing, for J. Franck and H. Hertz's ionization voltages are He, 20.5 volts; Ne, 16.0 volts; and Ar, 12.0 volts.

W. Kossel's arrangement of the electrons in the different atoms of low at. wt. is

H 1	He 2	Li (2)1	Be (2)2	B (2)3	C (2)4	N (2)5	O (2)6	F (2)7
Ne (2,8)	Na (2,8)1	Mg (2,8)2	Al (2,8)3	Si (2,8)4	P (2,8)5	S (2,8)6	Cl (2,8)7	
Ar (2,8,8)	K (2,8,8)1	Ca (2,8,8)2	Sc (2,8,8)3	Ge (2,8,8)4	V (2,8,8)5	Cr (2,8,8)6	Mn (2,8,8)7	

This may be compared with Table III. So long as no test is available for the stability of concentric rings of electrons, it is open to adopt any desired arrangement of electrons or rings. W. D. Harkins assumed that the relative abundance of the elements in meteorites and on the surface of the earth is dependent on the stability of the nuclei of the respective atoms, and on the stability of the aggregates of electrons. E. Rutherford believed that he has driven particles of mass 3 and charge 2 from light atoms, and inferred that these particles are of more importance than those of mass 4 in building light atoms. Against this, W. D. Harkins pointed out that at. wt. of the most abundant isotopes in F. W. Aston's list are divisible by 4, and only two are divisible by 3 as well as by 4; also the at. wt. of 87 per cent. of the elements in meteorites is divisible by 4; and but 0.77 are divisible by 3. F. Brössler estimated that the mass of the hydrogen nucleus is less than the four hydrogen

atoms from which it is derived, and that during the condensation of the hydrogen nuclei, the loss of energy is $0.029V^2$, where V denotes the velocity of light. Consequently, it is unnecessary to suppose that helium nuclei pre-exist in the nuclei of radioactive elements in order to account for the kinetic energy possessed by α -particles, for part of the energy liberated during the formation of helium nuclei within the atom from pre-existing hydrogen nuclei might be utilized in detaching the α -particles so formed and imparting to them their momentum. A. W. Hull, for example, obtains conclusions in accord with a statical theory from observations on X-ray spectra, while A. H. Compton obtains diametrically opposite conclusions

FIG. 14.—Maximum Number of Valency Electrons in the Atoms of the Elements.

in accord with a dynamical theory. J. W. Nicholson objected that coplanar concentric rings of vibrating electrons are unstable, so that if there are to be two or more rings of electrons in an atom, they cannot be in the same plane. This would make N. Bohr's theory untenable—*vide supra*. The periodic rule is taken to be represented by the periodic recurrence of rings of electrons of the same kind. The outer ring of electrons causes those electrons which take part in chemical combination. R. Abegg and G. Bodländer's normal and contra-valencies are represented by electrons which can be given up or taken on in forming compounds. W. Kossel represents this by Fig. 14. The abscissæ and ordinates represent the at. numbers of the different elements, and the arrows indicate by their length the

maximum number of electrons which each atom can give or receive in forming compounds. F. Urbach has discussed an analogous hypothesis.

The hypotheses of W. Ramsay, J. Stark, J. J. Thomson, G. N. Lewis, I. Langmuir, etc., favour the statical view of the structure of the atom. In **W. Ramsay's theory of rotating electrons**, the fixed electrons were assumed to rotate in circular orbits; and the valency electrons to rotate in small circles at definite places on the surface of the atom. The orbits of the latter were thus parallel to some equatorial plane fixed in the atom, the orbits of the different valency electrons need not necessarily have the same diameters; and while some electrons may revolve clockwise, others might revolve anti-clockwise relative to the nearest poles of the sphere. Electropositive elements differ from electronegative elements in the direction of rotation of the electrons. The formation of molecules was explained by the magnetic attraction due to the rotating electrons, which arranged themselves in the molecules so as to permit the maximum magnetic flux through the planes of the electronic orbits. W. E. Garner discusses a modification of this hypothesis. A. L. Parson also assumed that the electron itself is a rotating ring of negative electricity, and is therefore a minute permanent magnet, and he called such an electron a *magneton*. The magnetons at the surface of different atoms exert magnetic and electrostatic forces on each other which result in chemical combination. A. E. Oxley also suggested that the electrons revolve in small circles about stable positions in the atoms. A. H. Compton, A. D. Fokker, D. L. Webster, A. H. Crehore, K. Herrmann, H. S. Allen, W. Lenz, W. Pauli, etc., have discussed the magnetic polarity of atoms. T. R. Merton inquired if the orientation of the atoms in crystals is regular or at random, on the assumption that the atom has an axis perpendicular to the plane in which the electrons are rotating. If the α -particles are related to the orientation of the axis, the α -ray activity from the different faces of a radioactive substance might differ per unit area exposed. No difference was detected within the limits of the method of measurement available.

W. Ramsay in imagination materialized the electrons by stating that "electrons are atoms of the chemical element electricity; they possess mass; they form compounds with other elements; they are known in the free state, *i.e.* as molecules; and they serve as bonds of union between atom and atom." He symbolized it by E ; and the valency of an element is determined by the number of electrons which an element gains or loses under a given set of conditions. R. C. Tolman, M. von Laue, and H. A. Wilson have discussed the thermodynamics of what they call *electron gas*.

(a) In one form of **J. Stark's hypothesis** the units of positive electricity are supposed to be situated on the surface of the atoms, not as uniformly charged zones, but rather conc. at certain points, and the neutralizing negative electrons are assigned definite positions on or near the surfaces of the atoms. When two atoms are united

FIG. 15.—Saturated Valency.

together, the negative electrons hold the positive atoms each to each, as illustrated diagrammatically in Fig. 15, where the dotted lines represent tubes or lines of force. Otherwise expressed, **when two atoms are united chemically, they are held together by electrons common to both atoms**, each pair of electrons linking the atoms together are eq. to one univalent bond of the ordinary valency doctrine. In J. Stark's theory, compounds are formed when the lines of force from

one of the valency electrons stretches to the positive area on the other atoms. With strongly polar bodies, an electron is drawn almost wholly to the atom which holds it in combination. A primary valency is an effect of a pair of negative electrons whose field binds the atoms together. The stray electric field in the space about the molecule produces the so-called residual affinity.

(b) In J. J. Thomson's hypothesis of **directed valencies**, the electric forces which keep the atoms together originate in a *displacement* of the positive and negative electricity in each atom; and, as a result, each atom acts like an electric doublet and attracts another atom, much in the same way that two magnets attract one another.

J. J. Thomson's theory starts from the assumption that an atom is an aggregate of negative electrons with a sphere of positive electrification. The charges (i) may or (ii) may not counterbalance one another, leaving the atom either electrically neutral or polarized, that is, charged with a surplus of positive or negative electricity. A pair of balanced charges is called an **electric doublet**, and W. Sutherland suggested the hypothesis that the peculiar force exerted by an atom is the same as if each atom carried an electric doublet whose moment is characteristic of the atom. W. Sutherland's atoms therefore characterize compounds of the first class, but not the second. K. Kallmann and F. Reiche studied the passage of molecules with electric dipoles through unhomogeneous electric fields.

Fig. 16.—Unsaturated Valency.

The field of electric force about the molecules of a compound.—From the known properties of electrified bodies, it is inferred that a field of electric force must envelop each atom no matter whether the opposite charges wholly or partially counterbalance one another, because the positive and negative electrons are *ex hypothesi* unable to destroy one another. The neutralization of two opposite charges annuls the electric field at a comparatively large distance from the atoms. Coulomb's law applies only to comparatively large distances, and not at distances comparable with the dimensions of the atoms. Some unrecognized cause seems to prevent positive and negative electrons approaching within less than a certain distance. Consequently, even an electrically neutral atom will have a field of force which (i) will not be uniformly distributed about the atom; and which (ii) will probably diminish in intensity more rapidly than the inverse square of the distance. The field of force emanating from the charges in the atom will give rise to (a) *intramolecular attractions* whereby the charged atom affects the other atoms associated with it in the molecule; but it will also give rise to (b) *intermolecular attractions* because the field of force of an atom will also attract the atoms in other molecules, and so produce phenomena like the surface tension of liquids, latent heat of evaporation, cohesion of liquids and solids, etc. Accordingly, chemical compounds can be divided into two classes.

I. Non-polarized molecules with uncharged or neutral atoms.—The individual atoms of the molecule are neutral, for the constituent atoms are charged with equal amounts of positive and negative electricity, and there is no surplus or excess of the one kind over the other. The atoms are held together by one or more doublets on each atom. Among the **non-polar molecules** are H_2 , O_2 , He, N_2 , Cl_2 , CO, CO_2 , CS_2 , CCl_4 , C_6H_6 , N_2O , etc.

II. Polarized molecules, or molecules with charged atoms.—The individual atoms within the molecules carry an excess of positive or negative electricity so that the whole molecule is charged, and, accordingly, exerts larger forces upon the atoms of neighbouring molecules than would be the case if the atoms were neutral. There is supposed to be an actual transfer of an electron from one atom to another in those molecules. The chemical reactivity, specific inductive capacity, surface tension, cohesion, tendency to form molecular complexes, and other qualities of such compounds are found to be highly developed. Among the **polar molecules** are grouped H_2O , NH_3 , HCy , SO_2 , HCl , CH_3OH , C_2H_5OH , CH_3Cl , etc.

G. N. Lewis, R. W. G. Wyckoff, S. H. C. Briggs, and W. C. Bray and G. E. K. Branch also have emphasized the fact that there are two types of chemical compounds which can be designated polar and non-polar, and which they regarded as coinciding approximately with what are usually known as inorganic and organic compounds. These compounds are typified respectively by potassium chloride and methane. Nevertheless, some inorganic compounds are predominantly non-polar, and some organic compounds, at least in certain parts of their molecule, are strongly polar. G. N. Lewis contrasts the properties of the extreme members of these two types by means of Table IV. He continues: "All of these properties with respect to which fundamental distinctions have been made between the two types, and which seem so unconnected, are in fact closely related, and the differences

are all due to a single cause. Even before making any more special hypothesis we may very safely assume that the essential difference between the polar and the non-polar molecule is that, in the former, one or more electrons are held by sufficiently weak constraints so that they may become separated from their former positions in the atom, and in the extreme case pass altogether to another atom, thus producing in the molecule a bipole or multipole of high electrical moment. Thus in an extremely polar molecule, such as that of sodium chloride, it is probable that at least in the great majority of molecules the chlorine atom has acquired a unit negative charge and therefore the sodium atom a unit positive charge, and that the process of ionization consists only in a further separation of these charged parts.

If then we consider the non-polar molecule as one in which the electrons belonging to the individual atom are held by such constraints that they do not move far from their normal positions, while on the polar molecule the electrons, being more mobile, so move as to separate the molecule into positive and negative parts, then all the distinguishing properties of the two types of compounds become necessary consequences of this assumption, as we may readily show. From the fact that in the polar molecule "the constraints which operate against a separation of the charges are already weak, it follows that these charges may be further stretched in the electric field, and that bipoles or multipoles which already exist in the substance may, by rotation, orient themselves in the electric field, thus producing a large displacement current and therefore a high dielectric constant. Now as the difference between the dielectric constant of a substance and that of free space measures directly the number of free charges in the substance multiplied by the average distance through which these charges move under the influence of a definite electric field," it follows that the dielectric constants of polar substances must be relatively greater than those of non-polar type. Also it follows that polar substances may be readily ionized and will form ionizing solvents. That is, such substances are good conductors of electricity (electrophiles).

TABLE IV.—THE PROPERTIES OF POLAR AND NON-POLAR COMPOUNDS.

Polar.	Non-polar.
Mobile	Immobile
Reactive	Inert
Condensed structure	Frame structure
Tautomerism	Isomerism
Electrophiles	Non-electrophiles
Ionized	Not ionized
Ionizing solvents	Non-ionizing solvents
High dielectric constant	Low dielectric constants
Molecular complexes	No molecular complexes
Association	No association
Abnormal liquids	Normal liquids

The distribution of the electric charges within the molecule.—Each element has its own specific attraction for negative charges, thus, sodium exerts a less attraction for negative charges than chlorine; otherwise expressed, sodium is more electropositive than chlorine. With carbon monoxide, although the opposite charges on the two atoms neutralize one another, yet the oxygen has a greater attraction than carbon for a negative charge. Hence, a certain amount of work is available in the transfer of a negative charge from the atom in which the attraction is weak to an atom in which the attraction for the negative charge is strong. Accordingly, when a neutral electropositive atom is united with an electronegative atom, the negative charge tries to pass from the former to the latter and electrify it negatively. Why does not the transfer always take place? J. J. Thomson assumes that electricity

has an atomic structure, and must pass in definite units from one point to another, and therefore a whole charge must be transferred or none at all. He illustrates the action by diagram, Fig. 17. Each atom C and O carries a balanced positive and negative charge. The O is more electropositive than the C, and there is therefore a tendency for a negative charge to pass from the C to the O atom; but this tendency does not suffice to overcome the attraction of the positive charge carried by the C atom. This latter is diminished by bringing up another atom represented by the dotted line, Fig. 18. This helps the

FIG. 17.—Carbon monoxide, CO, with neutral atoms.

FIG. 18.—The charging of a carbonyl, CO, radicle.

passage of the negative charge across to the O atom. Thus, the atoms of a compound may be uncharged when isolated, and yet become charged when the compound is in a liquid state, or when the atoms are combined to form more complex molecules. The term **intramolecular ionization**, by the way, is applied by J. J. Thomson to the process by which the atoms of a molecule get charged electrically.

J. J. Thomson compares the two atoms of, say, carbon monoxide with the two coatings of a Leyden jar; so that the whole molecule behaves as if it were a Leyden jar of small capacity. It is known that the smaller the capacity of a jar, the greater the amount of energy required to transfer, say, q units of electricity into the jar. If the available energy be less than this, the transfer of, say, a single negative charge from a carbon to an oxygen atom will not occur, and *vice versa*. By increasing the capacity of the "jar" a transfer might occur which would otherwise be impossible. Hence, if another molecule be added to a certain atomic system, its capacity might be increased and accordingly less work might be required to transfer a charge from an electropositive to an electronegative atom.

Platinum tetrachlorodiammine, $\text{PtCl}_4(\text{NH}_3)_2$, is not an electrolyte, because its atoms are electrically neutral. Add another molecule of ammonia to get $\text{PtCl}_4(\text{NH}_3)_3$, and the resulting compound is an electrolyte with a mol. conductivity of 97; this number rises to 228 with the addition of another molecule of ammonia to form $\text{PtCl}_4(\text{NH}_3)_4$; and up to 553 when two more molecules of ammonia are added to form $\text{PtCl}_4(\text{NH}_3)_6$. Thus, as the molecules of ammonia are increased, the charges carried by the atoms increase rapidly. Carbon monoxide is neutral, but when it enters as a carbonyl radicle into organic compounds—like acetone, $(\text{CH}_3)_2\text{CO}$; aldehyde, CH_3COH ; etc.—it raises their specific inductive capacity because the CO radicle becomes charged on entering the compound. The proximity of other atoms increases the capacity of the system sufficient to allow the transfer in question. Mere contact with the other atoms promotes intramolecular ionization. In some cases, some of the radicles or atoms may carry one or more charges, and other atoms may be electrically neutral. The hydroxyl radicle, OH, may exist in a molecule in two states according as the oxygen atom carries one or two negative charges. If the oxygen atom carries one charge, the radicle $\text{O}^- - \text{H}^+$ will form an electric doublet; and if two charges—as is probably the case with water—there must be a positive charge on some other radicle not the hydroxyl group, and there will be two doublets in the molecule. J. J. Thomson suggests that the difference in these two states determines whether the OH radicle acts as an acid or as a base. Acidic hydroxyl is represented by $\text{O}^- - \text{H}^+$, and basic hydroxyl (of water) $\text{O}^{2-} - \text{H}^+$, for if the molecule $\text{RO}^- - \text{H}^+$ be in soln. and surrounded by H^+ and $\text{O}^- - \text{H}^+$ ions, arising from the dissociation of water, the H^+ ion of the given molecule would unite with the $\text{O}^- - \text{H}^+$ of the water, and leave an excess of H^+ ions in soln. so that the molecule $\text{RO}^- - \text{H}^+$ would have acidic properties; on the other hand, in the molecule $\text{R}^+ - \text{O}^- - \text{H}^+$, the $\text{O}^{2-} - \text{H}^+$ of the molecule would unite with the H^+ from the dissociation of the water and leave an excess of $\text{O}^- - \text{H}^+$ ions in the water, and the molecule would have basic properties. The more electropositive the element R in

the ROH molecule, the more likely is an electron to be transferred from the R to the O atom, and accordingly the more likely is the oxygen to acquire a second charge and show basic properties.

Valency electrons or corpuscles.—J. J. Thomson further suggests that each atom may contain negative electrons related to the atom in two ways: (i) *Immobile constitutional or fixed electrons*. Some of the electrons are firmly fixed at or near the core of the atom; they are not free to adjust themselves so as to cause the atom to attract other atoms into its neighbourhood; and they take no part in chemical reactions. (ii) *Mobile or valency electrons*. Some of the negative electrons are supposed to be located near the surface of the atom, and they are free to move about and set themselves into position under the influence of external electrical fields. They are linked with the central positive charge of the atom by lines of force. The mobile electrons, which J. Stark called *Valenzelektronen*, enable the atoms to hold on to one another and form a bond between joined atoms. The number of mobile corpuscles determines the valency of the atom so that a univalent atom has one, a bivalent atom, two, and a septivalent atom has seven mobile electrons. The mobility of the electrons is an essential condition necessary for one atom to exert any considerable attraction on another. For example, if an atom

FIG. 19.—Repulsion.

FIG. 20.—Attraction.

with one mobile negative electron—Fig. 19—and another atom with its negative electron—Fig. 20—were in contact, the two atoms would attract or repel one another as illustrated in the diagrams. If, however, the electrons are free to move, they will be driven apart until the positive charge

of the one atom is nearer to the negative charge of the other, and the atoms would then attract one another. The negative electron has very little inertia and, if free, can be driven round at once. The initial repulsion would therefore be momentary and attraction would be the final result. If the electron was fixed, it could not swing round without carrying the whole atom, which is a comparatively heavy body difficult to move. As a result, when the electrons are mobile, the atoms are kept together, but when the electrons are fixed, the atoms will have comparatively little attraction for one another. When the negative corpuscles of the atom are so firmly fixed as to be incapable of exerting any great attraction on other atoms surrounding it unless they are in particular positions, the valency of the atom is said to be sat., for the satisfaction of a valency is essentially the fixing of one of the mobile negative electrons.

Fixing the valency electrons.—Assume that each negative electron in an atom

FIG. 21.—Tube of Force of a Mobile Corpuscle.

is the origin of a line or tube of force. If the atom is alone, the line of force will return to the same atom and end on its own positive charge as illustrated diagrammatically (Fig. 21). The negative electron is still free to move. Consequently, an electron will not be fixed when the atom is by itself, but only when the line of force from the electron is anchored to an opposite charge on another atom B, Fig. 23. The electron is then deprived of its mobility, and is unable to attract another atom.

Case I. If the two atoms be electrically neutral, a similar tube of force will pass from each negative electron on each atom to the positive charge on the other atom, as illustrated diagrammatically (Fig. 23). Hence, with neutral atoms, for each tube of force which leaves an atom there will be a return tube—as many will go out as come in. Two electrons are involved in holding together two univalent neutral atoms. If the atoms are each bivalent, two tubes of force will leave each atom and two return; in general, **in compounds with neutral atoms the total number of lines of force between the constituent atoms is double the chemical valency**. This means that J. J. Thomson would represent each chemical valency by *two* bonds between the atoms of a molecule when the con-

stituent atoms are electrically neutral. It does not follow that if the atom A sends a tube of force to another atom B, it must receive one from the *same* atom B, for the return tube may come from *another* atom. The necessary condition is that **the number of tubes of force which leave an atom must be equal to the number which return.** With this understanding, certain combinations can be explained which appear to be anomalous in the light of the old valency hypothesis. If hydrogen be univalent, a combination like H_3 was considered impossible on the other hypothesis; but the hydrogen molecule has neutral atoms, with two tubes of force issuing from each. Consequently, the molecule H_3 , that is—

is thus quite compatible with the hypothesis, so also is a molecule H_n . Again, with monatomic silver, $AgCl$, $AgCl_2$, $AgCl_3$, and $AgCl_n$ are all possible valency compounds in this extension of the older valency hypothesis. The trouble with the hypothesis is that it apparently explains too much. There is no known evidence of the phenomenon—bi- or octo-valent carbon—with organic compounds, although a divided valency is sometimes observed in the arrangement of the atoms in crystals—*e.g.* the X-radiograms of magnetite.

Case II. If the two atoms be charged electrically.—We have seen that an electron will be fixed when its tube of force passes out of its atom and ends upon some other atom (Fig. 23). If one of the negative electrons (Fig. 22) be dragged from one atom, A, to the atom B, the electron would follow its tube of force which left the atom A, and the tube of force would shrink up in the atom B, and only one tube of force would connect the two atoms. When a number of electrons are transferred from one atom to another, the number of tubes of force between the two atoms will be halved, because after the transfer no tube of force will leave the electropositive atom, and none will enter the electronegative atom. The one atom, B, would thus be positively charged and the other, A, negatively charged. Hence, **in compounds with charged atoms, the number of tubes of force between the constituent atoms will be equal to the chemical valency.** The tube of force is then eq. to the bond or bar of the regular structural formulæ employed by chemists, and the valency bond is only applicable when the constituent atoms are charged electrically. If the constituent atoms are electrically neutral each valency bond must be doubled if it is to represent a tube of force. The chemist's hyphen or bond is thus related with the physicist's tube of force.

I. Langmuir has pointed out that valency may be exhibited in three different ways: (i) *Positive valence*, represented by the number of electrons an atom can relinquish; (ii) *Negative valence*, represented by the number of electrons an atom can receive; and (iii) *Co-valence*, represented by the number of pairs of electrons an atom can share with its neighbour.

Saturated and unsaturated compounds.—It follows from the preceding discussion that **when each of the mobile electrons in an atom is anchored by a tube of force to a neighbouring atom, the average attraction of that atom for other atoms is reduced to a minimum.** J. J. Thomson further shows that if the molecule of a compound is to exist in a stable form, (i) The molecules must not exert a sufficiently large attraction on the neighbouring atoms to cause them to unite and form other molecular systems. This will be the case when the work required to separate the two molecules under consideration is small compared with the average kinetic energy of the molecule at the temp. T . (ii) The attractions between the atoms of the molecules must be great enough to prevent a separation

FIG. 22.—Union of Charged Atoms.

FIG. 23.—Union of Neutral Atoms.

when the molecule collides with other molecules. This will obtain if the work required to separate the atoms is large compared with the average kinetic energy of the molecule at the temp. T . These conditions are greatly influenced by temp. Thus, with iodine vapour, the monatomic molecule may exist in a stable form at a high temp., and pass into more complex diatomic molecules at lower temp.

If carbon monoxide is a stable compound when electronegative carbon is united with the more electronegative element oxygen, why does not CCl_2 also form a stable compound? J. J. Thomson answers this question as follows: As already indicated, an atom, even when sat., must produce an electric field in its neighbourhood. This field must restrict the freedom of motion of molecules of the corpuscles in neighbouring atoms. If the electric field due to the oxygen atom in carbon monoxide be very strong, then, even though but two of the four mobile corpuscles of the carbon atom are bound to the oxygen by tubes of force, the other two will be exposed to so strong an electric field that their mobility is reduced. As a result, the attraction of the carbon atom on other atoms is reduced. The amount of residual attraction, so to speak, depends upon the strength of the electric field in the carbon atom produced by the oxygen atom. If the electric field with the CCl_2 -system be smaller than that produced in the CO -system, it follows that the latter will behave more like a sat. molecule than the former, and the carbon monoxide molecule, in consequence, might exist in a free state when the CCl_2 could not.

It might be argued that in a compound like ethane, C_2H_6 , with electropositive hydrogen atoms, and electronegative carbon atoms, the two carbon atoms are in a different electrical state, because the tubes of force from three hydrogen atoms end on each carbon atom, and a tube of force from one carbon atom must end on the other; accordingly, the potentials of the charges on the two carbon atoms must be different. This is illustrated diagrammatically in Fig. 24. Similar remarks apply

FIG. 24.—Ethane,
 C_2H_6 .

to acetylene and probably also to ethylene linkages. No phenomenon has yet been noticed which would justify this conclusion in the case of ethane, but in the case of doubly and triply linked combinations, several properties—mol. vol., index of refraction, etc.—are markedly different from what they are with the carbon atoms all singly linked together.

It is doubtful if every chemical bond involves the transfer of an electron from one atom to another; but, according to

J. J. Thomson, it is more probable that the electric force which keeps the atoms of a molecule together, is not due to one atom being charged positively and another negatively, but to the displacement of the positive and negative electricity in each atom. Thus, each atom acts like an electric doublet and attracts another atom much in the same way that two magnets attract one another. According to S. J. Bates, it is not necessary to assume that an electron moves from one atom to another for the atoms to be held together by electric forces, because (i) there is no evidence to justify the assumption that two atoms of an elementary gas like hydrogen, or two methyl radicles in ethane, are so different that one would be positively and the other negatively electrified. The two halves of each molecule react in an identical way; if they reacted differently, there should be more cases of isomerism than have been observed. (ii) Positive ray analysis shows that there is no relation between the greatest number of electrons an atom can lose and any chemical property such as the valency of an element; but it rather depends on its at. wt. Thus, the inert gas helium readily loses two electrons, and argon may carry one, two, or three positive charges, and krypton four. The carbon atom can carry no more than two charges, whereas it would be expected to carry four. (iii) In a dissociating gas, new molecules are being continuously decomposed while others are being formed; conductivity measurements, by J. J. Thomson, show no sign of any difference in the number of charged atoms or molecules than is present in a gas stable under the given conditions; P. J. Kirkby also concluded that the atoms of oxygen in water are not bound by electrostatic forces because the atoms of oxygen

when separated are not charged electrically ; nor did P. J. Kirkby and J. E. Marsh find any signs of the separation of charged atoms during the explosion of azoimide.

The effect of chemical combination on the structure of the atom.—A change in the internal structure of atoms in combination would explain why the properties of a compound may differ markedly from those of the contained elements ; but the numerous atomic or additive properties show that the contained atoms of a compound may retain their individuality in combination ; and the X-radiograms of crystals show that the contained atoms are juxtaposed and do not interpenetrate one another. Radioactivity also is not affected by chemical combination. The changes of energy involved in ordinary chemical actions are puny in comparison with those inherent in the atom as revealed by radioactivity. The free interatomic energy of the atoms in a molecule is but a small fraction of their intra-atomic energy. The loss or gain of electrons which occurs in chemical combinations must be accompanied by a more or less profound internal transformation of the atom ; this is evidenced on the ionic hypothesis in the difference which occurs between the activity of atoms and their ions ; a difference, say G. Ciamician and M. Padoa, *que la seule présence d'une charge électrique ne suffit pas à expliquer, quoi qu'on ait dit ou écrit à ce sujet*. An atom or molecule can acquire an electric charge without differing greatly from the neutral atom or molecule—e.g. ionized and non-conducting air. They add therefore that *the essence of chemical phenomena is a modification of the internal structure of the atom* ; and inquire : Does the form of the atom vary in different types of chemical combination or does it remain constant ? Certain elements retain the same chemical habit throughout the different types of combination. For example, carbon monoxide, hydrocyanic acid and the carbylamines, triphenyl-methane and the more complex analogous compounds do not differ essentially from the corresponding compounds of carbon in which the atom acts as tetravalent. By analogy we may say that the oxygenated compounds of chlorine possess common chemical characteristics in spite of the different amounts of oxygen contained, and the same thing is true of the compounds of nitrogen. On the other hand, certain other elements undergo so great a change of character in passing from one type of combination to another that one might think that the same atom consists of two or more different elements. Thus the knowledge of cupric salts could not enable us to predict the existence of the cuprous salts ; and how remarkable does thallium appear because of the great difference which exists between the thallous and the thallic compounds ! The same thing is true of the compounds of manganese, if we compare the manganic and the permanganic acids with the manganous salts ; or in the compounds of chromium, the derivatives of chromic acid with the salts of the sesquioxide. When we take into account such facts as these, it seems necessary to believe that in the case of some elements the form of the atom may vary according to the type of the combination, and consequently that there are elements whose atoms are polymorphous. In the case of some of them, such as carbon, for example, the variation of the valence does not imply the modification of the form of the atom, for the valencies remain free ; in the case of others, different forms of the atom correspond to different types of combinations ; for example, the atom of copper is dimorphous.

E. Kohlweiler argues that chemical processes have their origin in the nucleus of the atom, although the outer electrons may play a secondary part. If electrons were the only factors involved, the α -particle ought to be bivalent, whereas it has an affinity only for electrons. Ions occur in canal rays with positive charges which do not correspond with their chemical valencies. Nuclear structure and charge are the fundamental data of the chemical elements.

The constituent atoms of many compounds carry electric charges. The following indicates the chief evidence which has been adduced to support the view that the atoms in the molecules in some compounds are charged, and in other compounds uncharged. One of the most direct proofs of the existence of bodies in which the constituent atoms are electrically neutral is the absence of any sign

of electrical conductivity during the dissociation of, say, nickel carbonyl, carbon monoxide, oxygen molecules, etc. This result is confirmed by the positive ray analysis. On the other hand, with gases like hydrogen chloride, hydrogen cyanide, ammonia, etc., the opposite conclusion is drawn respecting the constituent atoms of the dissociating gas.

The specific inductive capacities, k , of compounds with presumably charged atoms, are markedly different from those with neutral atoms. Thus, the numerical value of $k-1$ is

Constituent atoms neutral.				Constituent atoms charged.			
Air	H ₂	CO ₂	CO	H ₂ O	NH ₃	HCl	CH ₃ OH
0.00059	0.00026	0.00094	0.00069	0.0070	0.0071	0.0025	0.0060

The specific inductive capacity of compounds whose molecules have charged atoms diminishes rapidly with a rising temp. For instance, with methyl alcohol, as the temp. rises from 93.2° to 148.6°, the value of $k-1$ diminishes more than 25 per cent. On the other hand, this constant is virtually independent of temp. with compounds whose constituent atoms are electrically neutral. The explanation turns on the fact that a molecule with charged atoms would try to set itself in a definite direction when placed in an electric field. The greater the proportion of the molecules of the compound which succeed in maintaining themselves in this position, the greater the specific inductive capacity. The mutual collisions of the molecules of a gas knock their axes out of line and prevent the axes of a certain proportion of the molecules from pointing in the right direction. The more violent the collisions the more the axes will be disturbed, and the less the relative number of molecules which contribute to the specific inductive capacity. Certainly, the molecules of a compound with uncharged atoms will have positive and negative charges induced at opposite poles when in an electric field, but the movements of the molecules will not disturb the relative position of these induced charges. The sphere might be knocked about by collisions, but that need not interfere with the electrification. Hence, the specific inductive capacity of compounds with uncharged atoms is not much affected by changes of temp.

As previously indicated, L. Bloch has shown that when a gas bubbles through a liquid such as water, alcohol, or acetone—in which the atoms of the molecules presumably carry electrical charges—the gas, as it emerges from the liquid, is mixed with positive and negative ions; whereas with liquids like paraffin oil or benzene, the emerging gas is not much affected. This is explained by assuming that fresh surfaces are continually produced as the gas bubbles through the liquid, and these surfaces have an amount of energy, per unit area, equal to the surface tension. Since this energy tends to a minimum, the effect of the action between the molecules which produce surface tension will be to promote any change which diminishes the surface tension at a fresh surface. Hence, the dissociation of a molecule of a compound will be favoured if a layer of dissociated atoms would give a smaller surface tension than the undissociated liquid; if the atoms of the molecules be charged the products of the dissociation will produce ions which are carried along and charge the gas electrically.

J. J. Berzelius considered that "the regular form of crystalline solids demonstrates an effort on the part of their atoms to touch one another by preference in certain points," and that this "can be no other than an electric or magnetic polarity." If one end of a crystal of tourmaline be dipped in liquid air, the cooled end contracts and sets up internal strains which must involve a rearrangement of the molecules inside the crystal. J. J. Thomson explains this by assuming that the molecules of tourmaline are electrified even at ordinary temperatures, and that the effect is masked by a conducting film which covers the crystal and acts as a shield. As soon as the internal arrangement of the crystal is disturbed, the skin can no longer counterbalance the internal electrification and a temporary electrification appears. Crystals of boracite, topaz, smithsonite, prehnite, scolezite,

aximite, etc., also exhibit pyroelectrification. The phenomenon may not prove Berzelius' hypothesis, but it certainly shows that a class of bodies may exist in which the atoms of the molecules are charged electrically.

Modifications of the theory have been proposed by K. G. Falk, R. F. Brunel, J. M. Nelson, H. T. Beans, H. S. Fry, W. C. Arsem, W. A. Noyes, C. R. Bury, E. J. Cuy, W. C. Bray and G. E. K. Branch, W. M. Latimer and W. H. Rodebush, G. N. Lewis, I. Langmuir, G. A. Perkins, H. I. Cole, H. Geiger, M. C. Neuburger, A. Sommerfeld, L. Zehnder, A. Lapworth, M. L. Huggins, J. Steiglitz, A. Duvallier, A. Magnus, W. Hughes, H. G. Grimm, G. L. Clark, A. D. Fokker, E. Yamazaki, R. A. Millikan, L. Meitner, J. K. Marsh and A. W. Stewart, R. M. Caven, J. D. M. Smith, W. O. Kermack and R. Robinson, J. N. Friend, etc.

Accepting the hypothesis that an atom of a univalent element has one disposable electron, that of a bivalent two, etc., J. J. Thomson (1922) argued that there must be in the crystal of a univalent element such an arrangement of atoms and electrons, that, for each atom, there is one electron; two electrons for each atom in a crystal of a bivalent atom; etc. He further assumed that this condition determines the forms in which the various elements can crystallize, and showed that, without further assumptions of physical constants such as dielectric constant, bulk modulus, frequency, etc., it is possible to calculate values for the crystal structure of the different elements which agree closely with observations.

Molecular compounds, or complex compounds.—In the so-called molecular compounds the simpler molecules are supposed to be held together by residual affinity (or secondary valencies) represented by stray electric fields around the molecules, and "these forces," says J. J. Thomson, will be exerted by the atom, not merely on the atoms which are associated with it in the molecule of a chemical compound, but also on the atoms in other molecules, giving rise to forces between the molecules, and thereby producing the intrinsic press. and surface tension of liquids, latent heat of evaporation, cohesion of solids and liquids, the rigidity of solids, and so on. These physical phenomena are the effects of forces between different molecules, whereas chemical affinity and chemical phenomena in general are the effects of forces having the same origin, but acting between the atoms of the same molecule. W. Jacobs, and R. D. Kleeman discussed the electric doublet theory in chemical reactions. H. W. Smith regarded secondary valency as the force binding molecules together, and not due to stray fields of force or to the operation of attractions acting according to some power of the distance. He asserts that the forces binding molecules are rhythmic in nature and not subject to ordinary electromagnetic laws. Secondary valency bonds have been discussed by D. Strömholm, F. Hocheder, J. A. N. Friend, G. F. Hüttig, S. H. C. Briggs, A. E. Lacomblé, etc.

In G. N. Lewis' theory of the cubical atom, it is postulated: (i) In every atom is an essential kernel which remains unaltered in all ordinary chemical changes and which possesses an excess of positive charges corresponding in number to the ordinal number of the group in the periodic table to which the element belongs. (ii) The atom is composed of the kernel and an outer shell, which, in the case of the neutral atom, contains negative electrons equal in number to the excess of positive charges of the kernel, but the number of electrons in the shell may vary during chemical change between zero and eight. (iii) The atom tends to hold an even number of electrons in the shell, and especially to hold eight electrons which are normally arranged symmetrically at the eight corners of a cube. A diagrammatic representation of the atoms ranging from lithium to fluorine is shown in Fig. 25. Lithium has one normal positive valence represented by one electron which can be readily detached; fluorine has one normal negative valence and seven contra-valencies; it can therefore readily take up another electron, completing a group of eight; it then resembles an atom of neon with the difference that (i) the fluorine has then one negative charge whereas neon is neutral; and (ii) the nuclear charge is not so great. If the seven electrons be removed from fluorine, it resembles an

atom of helium except for the nuclear charge. It is further assumed that two or eight electrons are very stable; and hence the inertness of the helium family. Every other type of atom can readily receive or relinquish electrons formally to resemble the members of the helium family. Thus, an atom of sodium by relinquishing one electron formally resembles neon, while an atom of sulphur by receiving two electrons formally resembles argon. When a lithium atom has given up one electron, the residue Li^+ is regarded as the kernel of the atom which is supposed to contain three positive charges and two electrons. Similarly with the atoms of the

FIG. 25.—G. N. Lewis' Theory of Cubical Atoms.

other elements. In chemical combination, say HCl , or LiCl , the more electropositive element gives one electron to the electronegative element so as to make a group of eight. Similarly, an atom of calcium, with its two detachable electrons, gives up two electrons to an atom of oxygen to form a group of eight, forming a molecule of calcium oxide. In forming ammonia, three hydrogen nuclei are attached by means of electrons to the unoccupied places on the nitrogen atom; at the same time, the nitrogen atom is able to give an electron to another hydrogen nucleus. The result is an NH_4 -group with one readily detachable electron. The NH_4 -group thus resembles the atom lithium, sodium, etc. From observations on the compressibility of salts of the alkali metals, A. Landé and co-workers also assumed that the atom has a cubic symmetry; and it is suggested that the electrons are arranged at the corners of a cube where they can rotate in orbits while preserving the cubic symmetry of the atom. These tridimensional models were criticized by A. Smekal, and A. Sommerfeld discussed the equilibrium of systems of cubic atoms. J. J. Thomson showed that when the electrons are arranged symmetrically in an atom, the displacement of an electron by an external force will always be in the direction of the force, and the ratio of the displacement to the force will be independent of the direction of the force. The same condition does not hold when the atom is unsymmetrical, for the displacement of the electron is not in the direction of the force.

I. Langmuir has remodelled the preceding hypotheses, and produced a statical hypothesis which is known as **I. Langmuir's octet theory of atoms**. It is closely related to G. N. Lewis' cubical theory, and includes many of the suggestions from W. Kossel's dynamical theory. It is assumed that the chemical inertness, the high ionizing potential, the low b.p., etc., of helium show that the arrangement of the electrons in helium is more stable than that of any other element. A pair of electrons thus represents a very stable group, and the evidence indicates that a similar pair of electrons is contained in the atoms of lithium, beryllium, etc. These two electrons are supposed to be symmetrical with respect to an equatorial plane, but not in the plane, Fig. 26. The symmetry is thus that of the tetragonal system like the earth with a polar axis

FIG. 26.—Helium Atom.

cd , and an equatorial plane ab . The continuity in the K - and L -radiations show that there is no abrupt change in the internal layers of electrons about the nuclei of the atoms of elements of low and high at. number. The properties of neon likewise show that its electronic system is more stable than that of any element other than helium, and its ten electrons are presumably arranged as a set of two and a set of eight. It is assumed that the great stability of the octet is a result of the geometrical symmetry of the arrangement of eight electrons at the corners of a cube. This explains why an arrangement of seven or nine electrons is not so stable.

The eight electrons arrange themselves in a second shell concentric with the other; four electrons in each hemisphere, but none in the equatorial plane, Fig. 28. The outer shell has twice the diameter of the inner one, so as to allow the same space for each cell. Each cell may hold two electrons, and in argon, the next member of the family to neon, has an atom like neon, but with a second layer of eight electrons, making 18 electrons in all. Outside this in the krypton atom is a concentric shell of 18 electrons, in the xenon atom there is a second layer of 18 electrons. Eight of the nine electrons in each hemisphere of krypton are placed symmetrically with respect to the polar axis and the electrons in the second shell; the ninth electron in each hemisphere goes to the polar axis. This also accounts for the position and properties of the iron family. In the niton atom there is a third shell with 32 electrons. The distribution of the electrons in the various shells is:

FIG. 27. — Outer Shell of Neon with Eight Cells.

FIG. 28. — Neon Atom.

		Layers of electrons.	Total electrons.
First shell	.	$2 = 2 \times 1^2$	2 Helium
Second shell	{1st layer	$8 = 2 \times 2^2$	10 Neon
	{2nd layer	$8 = 2 \times 2^2$	18 Argon
Third shell	{1st layer	$18 = 2 \times 3^2$	36 Krypton
	{2nd layer	$18 = 2 \times 3^2$	54 Xenon
Fourth shell	.	$32 = 2 \times 4^2$	86 Niton

The electrons in the different layers thus bear a simple relation to one another, $2(1+2^2+2^2+3^2+3^2+4^2)$. J. R. Rydberg arranged the atomic numbers of these elements in a similar series. The more or less concentric spherical shells have the same thickness so that their radii form an arithmetical series 1, 2, 3, 4; each shell is divided into cells of equal volume. The 1st shell has 2 cells; the second, 8; the third, 18; and the fourth, 32. The innermost cell has one electron per cell; the other cells may have as a maximum two electrons per cell. When two electrons occupy one cell, they are disposed at different distances from the centre of the atom. The inner cells must contain their maximum quota of electrons before the outer cells can contain any. In the outer shell, two electrons may occupy one cell provided all the other cells contain at least one electron. The arrangement of the electrons in the atoms of different elements is shown in Table V. Hydrogen has a single positive charge and a single electron. Its positive and negative poles form an electric doublet of high moment which tends to attract all other bodies, something like a small magnet. Thus at. hydrogen is strongly adsorbed by surfaces. By sharing their electrons, two hydrogen atoms can form a stable pair so that the atoms form diatomic molecules with a weak external field. As in G. N. Lewis' theory of cubical atoms, the chemical properties of lithium, beryllium, and boron are determined by their tendency to give up electrons, to form stable octets; while carbon, nitrogen, and fluorine *take up* electrons to form stable octets.

The theory explains the periodic properties of the elements including the eighth group and the rare earths; the magnetic properties of the elements; and the valency of polar and non-polar compounds. It is assumed that electrons contained in the same cell are nearly without effect on each other. But the electrons in the outside layer tend to line themselves up (in a radial direction) with those of the underlying shell because of a magnetic field probably always to be associated with electrons bound in atoms, as in Parsons' magneton theory. This attraction may be more or less counteracted by the electrostatic repulsion between the outside electrons and those in the underlying shell. The electrons in the outside layer also repel each other, and thus tend to distribute themselves among the available cells so as to be as far apart as possible. The actual positions of equilibrium depend on a

balance between these three sets of forces together with the attractive force exerted by the nucleus.

When the number of electrons in the outside layer is small, the magnetic attraction exerted by the electrons of the inner shells tends to predominate over the electrostatic repulsion, but when the atomic number and the number of electrons in the outside layer increase, the electrostatic forces gradually become the controlling factor. As a result, when there are few electrons in the outer layer these arrange themselves in the cells over those of the underlying shell, but where the outside layer begins to approach its full quota of electrons the cells over the underlying electrons tend to remain empty.

The properties of the atoms are determined by the number and arrangement of electrons in the outside layer and the ease with which they are able to revert to more stable forms by giving up or taking up electrons, or by sharing their outside electrons with atoms with which they combine. The tendencies to revert to the forms represented by the atoms of the inert gases are the strongest, but there are a few other forms of high symmetry such as those corresponding to certain possible

forms of nickel, palladium, erbium, and platinum atoms towards which atoms have a weaker tendency to revert (by giving up electrons only). The very stable arrangements of electrons corresponding to those of the inert gases are characterized by strong internal but unusually weak external fields of force. The magnetic and electrostatic forces are each very nearly internally balanced. The smaller the atomic number of the element the weaker are these external fields. The pair of electrons in the helium atom represents the most stable possible arrangement. A stable pair of this kind forms only under the direct influence of positive charges. The positive charges producing the stable pair in the order of their stability, may be: (a) The nucleus of any element; (b) Two hydrogen nuclei; (c) A hydrogen nucleus together with the kernel of an atom; (d) Two atomic kernels. After the very stable pairs the next most stable arrangement of electrons is the group of eight such as forms the outside layer in atoms of neon and argon. We shall call this stable group of 8 electrons the "octet." Any atom up to argon having more than two positive charges in its kernel tends to take up electrons to form an octet. The greater the charge on the kernel the stronger is this tendency. In exceptional cases, the octet can form about a complex kernel, that is, about a structure containing the kernels of two atoms bound together by a pair of electrons. Two octets may hold 1, 2, or sometimes even 3 pairs of electrons in common. A stable pair and an octet may hold a pair of electrons in common. An octet may share an even number of its electrons with 1, 2, 3, or 4 other octets. No electrons can form parts of more than two octets.

The covalency of an atom is the number of pairs of electrons it shares with other atoms. If we represent by e the total number of available electrons in the outside shells of the atoms forming a given compound, and let n be the number of octets formed, holding p pairs of electrons in common, we see that, for every pair of electrons shared, there is a saving of $2p$ in the number of electrons needed to form octets. We have, therefore, $e = 8n - 2p$, or $p = \frac{1}{2}(8n - e)$. Of course, electrons held by a hydrogen nucleus in common with an octet must not be counted in reckoning the value of p , since they do not result in any saving in the numbers of electrons required to form octets. The two hydrogen nuclei of water always tend to hold pairs of electrons, but not octets, consequently n is unity for the oxygen atom. There are six available electrons in the oxygen atom, and two in the hydrogen atom, hence $e = 8$, and p is zero. No electrons are therefore held in common between octets. The two hydrogen nuclei are held by electrostatic attraction on two pairs of the electrons forming the octet. The water molecule may, therefore, be pictured as a cube with two hydrogen nuclei hanging on to opposite edges. This structure indicates that water forms molecules in which the electrostatic forces are almost completely compensated internally. All the electrons form an octet, and hence the molecule should have a rather weak external field of force. Water should, therefore, be easily volatile and should not be a good conductor of electricity. But the lower symmetry of the molecule, as compared with the neon atom, shows that the b.p. should be much higher. In the formation of carbon dioxide and nitrous oxide, the black discs in Fig. 29 show those electrons which share equally a position in both octets when the atoms come together. There is a remarkable resemblance between the two, the stability and properties should therefore be similar. This deduction is confirmed by the comparison of the properties of the two compounds in Table VI. In addition, there are the two hydrates, $N_2O \cdot 6H_2O$, and $CO_2 \cdot 6H_2O$; the heats of formation are respectively 14.9 and 15.0 Cals. per mol; the surface tensions are the same at 12.2° and 9° respectively. The refractive indices are 1.193

FIG. 29.—Formation of Molecules of Nitrous Oxide and Carbon Dioxide.

and 1.190; the dielectric constants, 1.598 and 1.582; the magnetic susceptibilities are the same, 0.12×10^{-6} ; and the heat conductivity at 100° the same, 0.056. Carbon monoxide is regarded as an unsaturated compound, but it is really comparatively inactive. Its low b.p. shows that its external field is weak; and this corresponds with its low solubility. From the above formula, $n=2$, $e=10$, and $p=5$. This also suggests an unsaturated compound. Structurally it resembles nitrogen and the comparison of the properties of nitrogen and carbon monoxide. Table VI emphasizes the similarities. The resemblance in the mol. structure of

TABLE VI.—COMPARISON OF THE PROPERTIES OF CARBON DIOXIDE AND NITROUS OXIDE; AND OF NITROGEN AND CARBON MONOXIDE.

Property.	N ₂ O	CO ₂	CO	N ₂
Critical press.	75	77	35	35
Critical temp.	35.4°	31.9°	-151°	-146°
Critical vol.	—	—	5.05	5.17
Viscosity	148×10^{-6}	148×10^{-6}	163×10^{-6}	166×10^{-6}
Sp. gr. at -20°	0.996	1.031	—	—
Sp. gr. at 10°	0.856	0.856	—	—
Sp. gr. at b.p.	—	—	0.793	0.797
Solubility water at 0°	1.305	1.780	3.5	2.46
Solubility alcohol at 15° . .	3.25	3.13	—	—
F.p.	—	—	-207°	-213°
B.p.	—	—	-190°	-195°
Mol. number	22	22	14	14

carbon monoxide, nitrogen, N₂, and nitric oxide is emphasized by the diagrams, Fig. 30. Nitric oxide has 15 electrons—one more than nitrogen, N₂, or carbon

FIG. 30.—Molecular Structure of Carbon Monoxide, Nitrogen, and Nitric Oxide.

monoxide. O. R. Foster described a number of atom models based on I. Langmuir's hypothesis.

I. Langmuir applies the hypothesis to a great number of compounds—e.g. the phosphorus acids, sulphur acids, nitrogen oxides, etc. In many compounds, the co-ordination number and the covalence are identical, and the octet theory then corresponds exactly to A. Werner's theory, just

as for organic compounds it is eq. to the ordinary valency theory. In hydrofluoroboric acid, HBF_4 , $n=5$, $e=32$, $p=4$; each fluorine atom thus shares a pair of electrons with the octet of the boron atom—the covalence is 4. In ammonium fluoride, $n=2$, $e=16$, and $p=0$; the four hydrogen nuclei thus attach themselves to the nitrogen octet giving rise to the positive ion NH_4^+ ; and since chlorine has a complete octet it becomes a negative Cl^- ion. Hence, ammonium chloride resembles a sodium chloride, the central nitrogen atom has a covalence of 4. In platinous tetramminodichloride, $n=7$, $e=48$, $p=4$. Four NH_3 -radicles are thus attached directly to the platinum, each sharing a pair of electrons; the nitrogen and platinum have each a covalence of four, and the chlorine atoms become ions.

Compounds having the same number of atoms, and the same total number of electrons arranged in a similar manner, are said to be **isosteric compounds**—*isos*, equal; *στερεός*, solid—e.g. nitrous oxide and carbon dioxide. The essential differences between isosteric molecules are confined to charges on the nuclei of the constituent atoms. Electrically charged groups of atoms or even single atoms may be isosteric:

Type 1, H^+ , He , Li^+ ; type 2, O^{++} , F^+ , Ne , Na^+ , Mg^{++} , Al^{+++} ; type 3, S^{++} , Cl^+ , A , K^+ , Ca^{++} ; type 4, Cu^+ , Zn^{++} ; type 5, Br^+ , Kr , Rb^+ , Sr^{++} ; type 6, Ag^+ , Cd^{++} ; type 7, I^+ , Xe , Cs^+ , Ba^{++} ;

type 8, N_2 , CO , CN' ; type 9, CH_4 , NH_4' ; type 10, CO_2 , N_2O , N_3' , CNO' ; type 11, NO_3' , CO_3'' ; type 12, NO_2' , O_3 ; type 13, HF , OH' ; type 14, ClO_4' , SO_4'' , PO_4''' ; type 15, ClO_3' , SO_3'' , PO_3''' ; type 16, PO_3' ; type 17, S_2O_6'' , P_2O_6''' ; type 18, S_2O_6' , P_2O_7''' ; type 19, SiH_4 , PH_4' ; type 20, MnO_4' , CrO_4'' ; type 21, SeO_4' , AsO_4'' .

Where isosteric groups or molecules have the same charges, they are **isoelectric**, and their properties are comparable—e.g. N_2 and CO —but when the charges are unlike, the resemblance may show itself as a similarity in crystalline forms.

The following cases of crystalline isomorphism are thus predicted by the theory and are found to exist according to published crystallographic data: $NaF-MgO$; KNO_2-KNCO ; KNO_3-SrCO_3 ; $KClO_4-SrSO_4$; $NaHSO_4-CaHPO_4$; $MnSeO_4 \cdot H_2O-FeAsO_4 \cdot 2H_2O$, etc. The following cases are predicted by the theory, but cannot yet be tested because of lack of available data: MgF_2-Na_2O ; $K_2S-CaCl_2$; $NaClO_3-CaSO_3$; $KHSO_3-SrHPO_3$; $Na_2S_2O_6-Ca_2P_2O_6$; $Na_2S_2O_7-Ca_2P_2O_7$; etc. Carbonates and sulphites are not isomorphous, the covalence of the central atom being 4 and 3 respectively. Nitrates and chlorates are not isomorphous, the covalency of the chlorine being 3 in chlorates. There are some disagreements—*vide* the plagioclases.

G. N. Lewis' and I. Langmuir's theory or analogous theories have been discussed by S. C. Bradford, A. E. Oxley, W. M. Latimer and W. H. Rodebush, E. C. Kemble, N. R. Campbell, H. Tertsch, A. W. Stewart, C. Schmidt, H. Teudt, R. N. Pease, F. Hocheder, E. Neusser, O. Hinsberg, A. C. Crehore, E. D. Eastman, H. S. King, G. A. Perkins, H. I. Cole, J. A. Wasastjerna, J. Steiglitz, J. Moir, D. L. Webster and L. Page, R. G. W. Norrish, C. R. Bury, etc. A. O. Rankine showed that the viscosity data and X-ray crystal data are consistent with G. N. Lewis' and I. Langmuir's hypothesis; but J. R. Partington stated that the hypothesis is inconsistent with the sp. ht. of the gases. For example, the ratio of the two sp. ht. of a rigid molecule with three atoms in line should be 1.400, whereas the ratio of the two sp. ht. of carbon dioxide or nitrous oxide is 1.3. Similarly, for the rigid nitrogen molecule the ratio should be 1.667 instead of 1.400 actually observed. In consequence, A. W. C. Menzies has shown that supplementary hypotheses are necessary.

This discussion has not proved these speculations, it only makes them appear plausible; and it illustrates the invaluable aid which chemistry and meta-chemistry are receiving from the exercise of disciplined imagination. Naturally many have fallen before the temptation to confuse imaginary phenomena with demonstrated fact. Premature generalizations are rife, since, as a rule, the less the number of facts, the easier it is to generalize—and the more likely are those generalizations to be wrong. J. J. Thomson said:

The theory is not an ultimate one; its object is physical rather than metaphysical. From the point of view of the physicist, a theory of matter is a policy rather than a creed. Its object is to connect or co-ordinate apparently diverse phenomena, and, above all, to suggest, stimulate, and direct experiment. It ought to furnish a compass which, if followed will lead the explorer further and further into unexplored regions. Whether these regions will be barren or fertile, experience alone will decide; but at any rate, one who is guided in this way will travel onward in a definite direction and will not wander aimlessly to and fro.

The honesty of science.—Here, then, we are confronted with phantasmæ which would be banished at once if we were convinced that they were sterile conjectures and not pregnant hypotheses. The speculations probably make the best guess yet made about the ultimate constitution of matter. The relations between hypotheses and fact, though doubtful, are not altogether contradictory. Consequently, the defective hypotheses will be persistently attacked by hostile forces until they are either abandoned in favour of more successful rivals, or developed and strengthened into a more consistent and lasting form.

This struggle for existence is the life and strength of scientific hypotheses. Science may appear to lose influence when the fallacy of a prevailing hypothesis is demonstrated; but it holds a treasured reputation for honesty of purpose by frankly acknowledging and registering its mistakes. In the words of A. Sidgwick,

free from the fear of being found an impostor, science is able to challenge and to court correction. "As for the truth, it endureth, and is always strong; it liveth and conquereth for evermore. Truth is the strength, the kingdom, the power, and the majesty of all ages."—1 Esdras iv, 38.

CHAPTER XXVIII

BERYLLIUM OR GLUCINUM

§ 1. The Discovery and Occurrence of Beryllium or Glucinum

C'est à la géométrie que l'on doit en quelque sorte la source de cette découverte (de cet élément) ; c'est elle qui en fournit la première idée, et l'on peut dire que sans elle la connaissance de cette terre nouvelle n'eût point été acquise de longtemps, puisque, d'après l'analyse de l'émeraude par M. Klaproth, et celle du béril par M. Bindheim, on n'aurait pas cru devoir recommencer ce travail sans les fortes analogies ou même l'identité presque parfaite que le citoyen Haüy avait trouvées par les propriétés géométriques entre ces deux fossiles pierreux.—A. F. DE FOURCROY.

THE mineral **beryl** occurs in hexagonal crystals which are variously coloured white, yellow, blue, or pale rose-red, but more commonly green—the pale green varieties are known as *aquamarine*, and the dark green varieties, as *emerald*, which is familiar as a gem-stone. The so-called *golden beryl* is bright yellow. The beryls are all more or less impure forms of beryllium aluminosilicate, $3\text{BeO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$; the rich green colour is due to chromium. The minerals *daivdsonite*, *goschenite*, *rosterite*, and *vorobyevite* are also varieties of beryl. The *smaragd*, *σμάραγδος*, and the beryl, *βήρυλλος*, were known to the ancients as ornamental gem-stones ; they are frequently mentioned in the Bible, and we are there told that the smaragd, or *emerald*, was assigned the fourth place in the breastplate of the high-priest of the tabernacle. Theophrastus, in his *Περὶ Λίθος*, about the third century B.C., wrote about the smaragd, and it is generally assumed that his description refers to our emerald. Although it is obvious that Theophrastus, and later, Pliny in his *Historia Naturalis*, written about the middle of the first century of our era, applied the term smaragd to many other minerals besides the emerald proper, Pliny said of one variety :

There is no stone more pleasing to the eye, for whereas the sight fixes itself with avidity upon the green grass, and the foliage of trees, we have all the more pleasure in looking upon the *smaragdus*, for there is no green in existence of a more intense colour than this ; and besides, of all the precious stones, this is the only one that feeds the sight without satiation. Even when the vision has been fatigued, with intently viewing other objects, it is refreshed by being turned upon this stone ; and lapidaries know of nothing that is more soothing to the eyes, for its soft green tints are wonderfully adapted for assuaging lassitude, when felt in those organs.

Pliny also referred to *beryllus* as having a like nature to that of the emerald. D. A. MacAlister¹ has described the locality known as Cleopatra's Emerald Mines of Jebel Sikait, Etbai, which have been worked over 2000 years. A. B. de Boot applied the name *aquamarine* to a sea-green coloured variety. From the old analyses of T. Bergman,² F. C. Achard, J. J. Bindheim, M. H. Klaproth, and L. N. Vauquelin, beryl was regarded as a calcium aluminium silicate ; while beryl and smaragd were regarded as two distinct mineral species. R. J. Haüy first suspected the identity of emerald and beryl from the sameness of their crystallographic and other physical characteristics, and he therefore invited L. N. Vauquelin³ to analyze these minerals ; and as a result, the latter opened his memoir : *De l'aigue marine ou béril, et découverte d'une terre nouvelle dans cette pierre*, with these words :

Le citoyen Haüy, dit-il dans son mémoire lu à l'Institut le 26 pluviôse an VI, ayant trouvé une conformité parfaite entre la structure, la dureté et la pesanteur du béril et de

l'émeraude, m'engagea, il y a quelques mois, à comparer aussi ces deux pierres par les moyens chimiques, pour savoir si elles étaient composées de mêmes principes et dans les proportions semblables.

L. N. Vauquelin found that *la terre du béril*, as he called it, can be separated from aluminium hydroxide by boiling the soln. with potassium hydroxide; and it differs from aluminium hydroxide in furnishing salts with a sweet taste, in forming no alum, in being soluble in ammonium carbonate, and in not being precipitated by potassium oxalate or tartrate. The editors of the *Annales de Chimie*, in which Vauquelin's paper was published, suggested the name *glucine* from γλυχίς, sweet, in reference to the sweet taste of the salts. L. N. Vauquelin adopted this term with some reluctance: he referred, in a footnote, to the proposed name *glucine*, and later still, he employed this term—possibly because of some pressure from the editors of the *Annales*. H. F. Link objected to the use of the proposed name on account of its resemblance to “glycine,” already in use for something else. M. H. Klaproth added that the sweetness of the salts of *la terre nouvelle* is not unique with that element, for the salts of yttria are also sweet, and he claimed that *Beryllerde* is a preferable term. A. G. Ekeberg agreed with M. H. Klaproth; and J. F. Gmelin translated the French *glucine* into the German equivalent *Susserde*. Thereafter, the term *Beryllerde*, obviously translated from L. N. Vauquelin's *la terre du béril*, was employed in Germany, and *glucine* in France. F. Wöhler employed the term *beryllium* for the metal which he isolated in 1828. In other countries there has been a kind of struggle for existence between the terms *beryllium* and *glucinum*, and neither designation has yet ousted the other. In 1905, J. L. Howe argued in favour of the latter, C. L. Parsons in favour of the former, and this is emphasized in the monograph: C. L. Parsons, *The Chemistry and Literature of Beryllium* (Easton, Pa., 1908). Argument is of no avail because the choice of terms is largely a question of temperament.

T. Richardson⁴ reported that the Aberdeen mineral, davidsonite, contained a new element which he called *donium*; and H. S. Boase, an element *treenium*. M. F. Heddle identified donium with beryllium.

Numerous analyses⁵ of the different varieties of **beryl** have been reported in addition to those to which allusion has been made. Some gigantic beryls have been reported in the United States—one found at Grafton (New Hampshire) is said to have weighed 2900 lbs., and another from the same locality, 1076 lbs. Other deposits are at Ackworth (New Hampshire), Royalston (Massachusetts), Albany (Maine), Haddam (Connecticut), Lieperville and Chester (Pennsylvania), Stony Point (North Carolina), Amelia Court House (Virginia), Coosa County (Alabama), Black Hills (Dakota), and in Chaffee County and Jefferson County (Colorado). Beryls are found in Cornwall (England), Kinloch Rannoch, Braemar, and Cairngorm (Scotland); several places in Ireland; Limoges (France); Finbo and Broddbo (Sweden); Bodenmais and Rabenstein (Bavaria); Elba; East Indies; etc. Beryl usually contains between 9 and 16 per cent. of beryllia; up to about 2 per cent. of lithia has been reported in numerous samples; W. Vernadsky's analyses showed the presence of up to 3.6 per cent. of caesia, and 1.3 per cent. of rubidia. W. A. Tilden found that up to about 6.7 vols. of gas were evolved when beryl was heated, and most of this was carbon dioxide. R. J. Strutt, and A. Piutti have measured the helium which can be driven from beryl.

The beryllium hydro-aluminosilicate, BeHAlSiO_5 , occurs as the mineral **euclase** in Brazil, South Urals, and the Austrian Alps. This rare mineral was analyzed by J. J. Berzelius,⁶ J. W. Mallet, and A. Damour. These analyses show 16.97 to 21.78 per cent. of beryllia. Beryllium occurring as a simple silicate, Be_2SiO_5 , is represented by the mineral **phenacite** with from 44.46 per cent. of beryllia,⁷ which was named from φέναξ, a deceiver, on account of its resemblance to quartz. It is found at Mount Antero (Colorado), at Framont (Vosges), in the emerald mines of the Urals, etc. It is also found in the mineral **bertrandite**, beryllium hydrosilicate, which approximates in composition, $\text{Be}_3(\text{BeOH})_2\text{Si}_2\text{O}_{10}$, it has 40–43 per cent. of beryllia. Phenacite is found at Barbin (Nantes), Pisek (Bohemia), Mount Antero (Colorado), and at Stoneham (Maine).⁸ The analyses of the silicate minerals

leucophane, $\text{Na}(\text{Be}, \text{F})\text{Ca}(\text{SiO}_3)_2$, by H. Erdmann,⁹ C. F. Rammelsberg, and W. C. Brögger; and of **meliphane**, or **melinophane**, or **meliphanite**, $\text{NaCa}_2\text{Be}_2\text{FSi}_3\text{O}_{10}$, by R. Richter, C. F. Rammelsberg, and W. C. Brögger, show the presence of 10–14 per cent. of beryllia; **eudidymite**, analyzed by W. C. Brögger, and A. E. Nördenskjöld, and **epididymite**, $\text{HNaBeSi}_3\text{O}_8$, of 10–13 per cent. of beryllia; **gadolinite**, $\text{FeBe}_2\text{Y}_2\text{Si}_2\text{O}_{10}$, analyzed by G. Flink,¹⁰ show 5–11 per cent. of beryllia; **trimerite**, $\text{Be}(\text{Mn}, \text{Ca}, \text{Fe})\text{SiO}_4$, analyzed by G. Flink, 16–17 per cent.; **cyrtolite** and **alvite** show 14–15 per cent.; **allanite**, up to about 0.3 per cent.; **muromonite**, 5–6 per cent.; **erdmannite**, up to 4 per cent.; **foresite** and **arrhenite**, up to 1 per cent.; and **bityite**, up to 2 per cent. of beryllia. The two minerals: **danalite**, $(\text{Be}, \text{Fe}, \text{Zn}, \text{Mn})_2\text{Si}_3\text{O}_{12}\text{S}$, and **heivite**, $(\text{Be}, \text{Fe}, \text{Mn})_2\text{Si}_3\text{O}_{12}\text{S}$, have 13–14 per cent. of beryllia.

Beryllium aluminate, $\text{Be}(\text{AlO}_2)_2$, is represented by the mineral **chrysoberyl**, with 19–20 per cent. of beryllia found in river gravels along with beryl and phenacite in mica schists, etc., in Brazil, Ceylon, Urals, Orange County (U.S.A.), etc. It is generally a pale yellowish-green, and is principally used as a gem-stone; the dark green crystals from the Urals are called **alexandrite**. The crystals exhibit a peculiar dichroism, being leek-green or emerald-green by reflected light, and deep raspberry-red or violet in transmitted light. They also appear red in gaslight, and green in daylight. The chatoyant bluish-white opalescent variety from Ceylon is known as *cat's-eye*, and the variety with a wavy opalescence, **cymophane**—from *κύμα*, a wave. Sodium beryllium phosphate, NaBePO_4 , is represented by **beryllonite**, from Maine; it has 19–20 per cent. of beryllia; calcium beryllium fluo-phosphate, BeCaFPO_4 , is represented by the gem-stone **herderite**, or **allogonite**, from Maine and Saxony; it has 15–16 per cent. of beryllia; the rare **hamlinite**, or **bowmanite**, which occurs with herderite and bertrandite, is a beryllium aluminium hydrofluophosphate. The native basic borate **hambegite**, $\text{BeOH} \cdot \text{BeBO}_3$, contains about 53 per cent. of beryllium oxide; and the aluminoborate, **rhodizite**, contains about 10 per cent. of beryllium oxide. J. W. Mallet¹¹ found the Virginian tantalum-niobate, *sipylite*, had 0.62 per cent. of beryllia. The complex carbonate, *tengerite*, may carry up to 9–10 per cent. of beryllia.

Beryllium is not very abundantly distributed in nature, but small quantities are found in a great many minerals; and if it had been specially sought in the more frequent mineral and rock analyses, or if some simple method of separating it from aluminium had been known earlier, it is probable that the reports of its occurrence in small quantities would be much more extensive. The beryllium minerals usually occur in granitic rocks. Beryllium has also been found in the zirconium minerals *alvite* and *cyrtolite*. O. Boudouard reported traces of beryllia in monazite sands, T. L. Phipson reported 0.33 per cent. in some aluminous schists. A. Bécamp found a trace of beryllia in the sulphur waters in the district of Alais. J. N. Lockyer found lines corresponding with beryllium in the spectrum of the sun; M. Pomier in the waters of Antiveille (Basses-Pyrénées); and M. Mazade, in the waters of Nérac.

§ 2. The Extraction of Beryllia

Beryllium is usually derived from beryl. Although there are minerals richer in this element, they are scarce and costly. G. Krüss and H. Moraht¹ treated finely powdered leucophane, suspended in water, with conc. sulphuric acid, and separated the beryllium from the resulting soln. as described below. C. James and G. A. Perley also digested gadolinite in conc. sulphuric acid. Beryl, however, is usually the cheapest and most convenient source of beryllium. The metal is not usually extracted directly, but is separated from the silica, alumina, etc., as oxide or a convenient salt. P. Lebeau's process is perhaps the most direct one yet proposed. He heated a mixture of beryl with half its weight of calcium carbide in an electric arc-furnace, and washed out the by-products with a mixture of hydrofluoric and sulphuric acids, and there remained 90–95 per cent. of the theoretical yield of beryllium. Reduction with carbon alone was not so satisfactory. Much of the silica volatilizes when beryl is heated in the electric arc-furnace.

In H. Debray's process, briquettes were made from a mixture of powdered beryl, carbon, and oil, and heated in a stream of chlorine, when carbon dioxide, silicon tetrafluoride, and iron, aluminium, and beryllium chlorides were evolved. C. A. Joy tried the process but did not recommend it. Powdered beryl is not

attacked by any single acid, excepting hydrofluoric acid. The mineral is usually heated with a flux—alkali hydroxides, alkali carbonates, calcium or potassium fluoride, or ammonium fluoride—in order to get the mineral in a form readily attacked by acids so as to get the beryllium all in soln. C. A. Joy tried many of these methods of breaking up the mineral. The fluoride fluxes have the advantage of readily removing the excess of silica as silicon tetrafluoride, and C. A. Joy found that the treatment with potassium fluoride and sulphuric acid is an excellent method except for the cost of the acid, to which might be added the high cost of platinum vessels. With the calcium fluoride processes, the large amount of calcium compounds introduced complications. L. N. Vauquelin, G. Wyruboff, J. H. Pollok, and C. L. Parsons and S. K. Barnes used alkali hydroxide; H. N. Warren, sodium carbonate; H. Debray, quicklime; J. Gibson, ammonium hydrofluoride; W. Gibbs, potassium hydrofluoride; G. Scheffer, a mixture of calcium fluoride and sulphuric acid; and P. Lebeau, calcium fluoride in a graphite crucible in an electric furnace. L. Burgess heated the ore with carbon, and volatilized the beryllium as chloride by treating the product with hydrogen chloride; H. S. Booth and G. G. Marshall heated a mixture of the crushed ore with an alkali earth halide at a temp. at which beryllium halide is formed.

P. Berthier heated an intimate mixture of powdered beryl and marble in a high temp. furnace; H. Debray used a mixture of beryl and calcium oxide, which virtually amounts to the same thing. C. A. Joy found the crucible was not so much attacked if calcium sulphate is also included in the mixture. The resulting glass is decomposed by nitric acid. C. A. Joy also tried fusion with litharge, followed by treatment with nitric acid, and fusion with manganese dioxide followed by treatment with sulphuric acid; but he did not recommend any of these processes.

According to C. A. Joy,² the best results are obtained by fusing an intimate mixture of powdered beryl with twice its weight of potassium carbonate. H. N. Warren used sodium carbonate as a flux; and C. A. Joy tried a mixture of sodium and potassium carbonates. An essentially similar method of opening up beryl was employed by G. Klatzo, L. F. Nilson and O. Pettersson, E. Hart, C. L. Parsons, etc. L. N. Vauquelin fused the powdered mineral with three times its weight of potassium hydroxide; G. Wyruboff, and C. L. Parsons recommended the same opening agent. A silver, nickel, or iron crucible can be used. The powdered mineral is fused with sodium carbonate in a fireclay crucible and the molten mass poured out to cool on an iron plate. The powdered mass is washed with water to remove soluble alkali salts—a little beryllium is lost at the same time. The residue is treated with an excess of sulphuric acid. The soln. is evaporated and heated on a sand-bath until the acid begins to fume. The cold residue is extracted with hot water, and the insoluble silica rejected. The mother liquid is evaporated until alum begins to crystallize from the soln.; on standing, a large proportion of the aluminium separates as potash alum. Beryllium forms no alum. The iron in soln. is oxidized with a little potassium chlorate or nitric acid. A mixture of aluminium, ferric, and beryllium hydroxides is then precipitated by adding a slight excess of ammonia. Several methods are now available for separating the alumina and beryllia. H. T. S. Britton found a 90 per cent. separation of alumina and beryllia is possible by a crystallization of the former as potassium alum.

According to H. Copaux's method of separation, the finely powdered mineral is heated at 850° for half an hour with twice its weight of sodium fluosilicate. The product, which consists of silica and the double fluorides of sodium and aluminium and sodium and beryllium, is extracted three times with boiling water. The extract is filtered, and to the filtrate boiling aq. sodium hydroxide is added in slight excess. The oxide of beryllium precipitated, along with a little alumina and silica, is dissolved in sulphuric acid, and beryllium sulphate crystallizes out on concentrating the soln. In this way 90 per cent. of the beryllium in the beryl is recovered. For the estimation of beryllium in beryl, 5 grms. of the powdered mineral are treated as above with 20 grms. of sodium fluosilicate. The precipitation with sodium hydroxide is omitted and an aliquot portion (300 c.c. out of 1 litre) of the filtered aq. extract is evaporated with sulphuric acid until white fumes appear. The residue is treated with water, and an excess of ammonia is added. If the precipitate contains a

noticeable quantity of iron it is redissolved in acetic acid and the iron removed by means of nitroso- β -naphthol. The filtrate is boiled and made alkaline with ammonia, and the precipitate is filtered off, dried, ignited, and weighed. Any silica present is removed by treatment with hydrogen fluoride, and the aluminium and beryllium are separated by fusion with sodium carbonate, etc.

(1) L. N. Vauquelin³ found that while ammonium carbonate precipitates both metals as hydroxides or carbonates, the beryllia alone dissolves in an excess of that reagent. A. Zimmermann showed that the presence of ammonium chloride favours the separation. This reaction has been studied by C. A. Joy, G. Scheffer, A. Hofmeister, F. Toczyksky, etc. T. Scheerer showed that the small quantity of iron dissolved by the ammonium carbonate soln. can be precipitated by ammonium sulphide. (2) J. J. Berzelius, and H. Rose found that with a boiling soln. of an ammonium salt, beryllia goes into soln. while alumina remains insoluble. This reaction has been studied by A. Hofmeister, E. Hart, and J. Weeren. (3) C. Renz noted that both aluminium and beryllium are precipitated by methyl- or ethylamine, but alumina is alone dissolved by an excess of the precipitant, the beryllia remaining insoluble. In 1880, C. Vincent recommended dimethylamine for the same purpose. (4) C. Rössler found that in the presence of citric acid, beryllia is alone precipitated by ammonium phosphate. (5) According to H. Rose, (a) tartaric acid, and other organic acids which retard the precipitation of iron and aluminium hydroxides, have no influence on the beryllium salt; (b) a boiling soln. of sodium acetate precipitates alumina but not beryllia; (c) barium carbonate precipitates alumina from a neutral soln., while the beryllia remains dissolved. (6) L. N. Vauquelin, C. G. Gmelin, and F. Schaffgotsch showed that a cold soln. of potassium hydroxide dissolves both alumina and beryllia; the former remains dissolved when the soln. is boiled, and the beryllia is precipitated. The reaction was studied by C. A. Joy, J. Weeren, and L. A. Aars. (7) P. Berthier found that sulphurous acid or ammonium sulphite dissolves the hydroxides of both metals in the cold, but when the soln. is heated, alumina is precipitated while the beryllia remains in soln. H. Böttinger showed that the method is unsatisfactory, though B. Glassmann rediscovered the discarded process. (8) C. A. Joy found alumina is alone precipitated by boiling a neutral soln. of alumina and beryllia with sodium thiosulphate, but the results were poor. (9) F. S. Havens found that aluminium chloride is not soluble in a soln. of hydrogen chloride in dried ether, while beryllium chloride dissolves therein. J. H. Pollok showed that the ether can be omitted, and the aq. soln. sat. with hydrogen chloride. (10) According to H. D. Minnig, a soln. of acetyl chloride in acetone precipitates aluminium chloride as $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, while iron and beryllium chlorides remain in soln. (11) F. Haber and G. van Oordt dissolved basic beryllium acetate in chloroform, leaving the acetates of iron and aluminium undissolved. (12) C. L. Parsons and W. O. Robinson separated basic beryllium acetate from the other acetates by means of its ready solubility in hot glacial acetic acid, and its insolubility in that reagent when cold. (13) C. L. Parsons and S. K. Barnes separated beryllium hydroxide by virtue of its solubility in a sat. soln. of sodium hydrogen carbonate, and the insolubility of iron and aluminium hydroxides in the same menstruum. The reaction was studied by F. Brau and G. van Oordt. (14) W. Gibbs suggested the use of sodium fluoride to separate quantitatively alumina and beryllia, and J. H. Pollok showed that the separation is exceedingly sharp. (15) L. E. Rivot proposed to separate iron from alumina and beryllia by reducing the iron oxide by heating the mixed oxides in a stream of hydrogen and dissolving out the metal with dil. nitric acid; J. P. Cooke proposed to volatilize the reduced iron in a stream of hydrogen chloride, and F. S. Havens and A. F. Way showed that the preliminary reduction by hydrogen is not necessary. (16) M. Schleir, E. A. Atkinson and E. F. Smith, and R. Burgass showed that iron can be quantitatively separated from beryllium by means of nitroso- β -naphthol. (17) P. Lebeau precipitated the iron in a nitric acid soln. with potassium ferrocyanide, the excess of ferrocyanide with copper nitrate, and the excess of copper with hydrogen sulphide. (18) H. Debray developed a separation dependent on the action of zinc on the mixed sulphates precipitating the aluminium as a basic sulphate. The reaction was studied by G. Scheffer. (19) E. Hart separated most of the iron and aluminium from the beryllium by the fractional precipitation with sodium carbonate; the great solubility of beryllia in a soln. of its own sulphate causes it to be the last to precipitate. (20) G. Wyruboff precipitates beryllium from its soln. in hydrochloric acid as a double oxalate with potassium; the aluminium and iron remain in soln. (21) According to P. E. Browning and S. B. Kuzirian, beryllium and aluminium nitrates are dissolved in a little water and boiled with amyl alcohol until the water has all evaporated; the beryllium nitrate dissolves, the aluminium nitrate remains insoluble. (22) By heating the mixed acetates to $160^\circ\text{--}170^\circ$, at 19 mm. press., beryllium acetate sublimes, iron and aluminium acetates do not. (23) According to G. van Oordt, aged beryllium hydroxide becomes insoluble in dil. soln. of acids and alkalis so that iron oxides can be extracted by the former, and alumina by the latter. (24) M. Wunder and P. Wenger fused the mixture of beryllia, iron oxide, alumina, and chromic oxide with sodium carbonate for 2-3 hrs. When the cold mass is extracted with water, the aluminium and chromic oxides pass into soln. The iron and beryllium oxides can then be separated by fusion with potassium hydrosulphate; and the iron precipitated from the aq. soln. of the cold cake by potassium hydroxide; and the filtrate, acidified, is treated with aq. ammonia when beryllia is precipitated. (25) G. Wyruboff found that the

double oxalate $2\text{BeC}_2\text{O}_4 \cdot 3\text{K}_2\text{C}_2\text{O}_4$ is only sparingly soluble, while the double oxalates of iron, aluminium, and chromium are nearly twice as soluble. (26) A. Classen electrolyzed an ammonium oxalate soln. of iron, aluminium, and beryllium; the current can be regulated so that the iron is reduced, and the aluminium precipitated as hydroxide by the ammonium carbonate produced while the beryllium remains in soln. (27) R. E. Myers precipitated iron in a mercury cathode by the electrolysis of a mixed slightly acid soln. of the sulphates of iron and beryllium.

The procedure recommended by C. L. Parsons is to saturate the neutral soln. of aluminium, iron, and beryllium salts with crystals of sodium hydrocarbonate; warm the liquid for 24 hrs., and to shake frequently. Most of the beryllium passes into soln., while the iron and aluminium are precipitated—completely if other salts be not present. By dissolving the residue left after filtration and repeating the treatment, practically all the beryllium will be found in the hydrocarbonate soln. Add ammonium sulphide to remove any dissolved iron, and dil. the soln. to five times its original volume. By blowing steam through the soln. until it has reached its b.p., the beryllium will be all precipitated as a granular basic carbonate easily washed. The precipitate has about 2 per cent. of occluded alkali which can be removed by re-solution in acid, followed by precipitation of beryllium hydroxide with ammonia.

To get rid of any rare earths, if such be present, G. Krüss and H. Moraht dissolved the beryllia in hydrochloric acid, neutralized with ammonia, added an excess of ammonium oxalate, and then sufficient dil. hydrochloric acid to dissolve the flocculent precipitate of beryllium oxalate. The oxalates of the rare earths remain insoluble. The soln. can be dropped into one of ammonium carbonate containing an excess of ammonia and ammonium oxalate and the filtrate treated with steam for the precipitation of basic beryllium carbonate. The hydroxide or basic carbonate can be used as a starting-point for the preparation of other beryllium compounds.

§ 3. The Preparation and Properties of Beryllium

About ten years after L. N. Vauquelin's discovery of beryllia, H. Davy ¹ tried to reduce this oxide (a) by fusing it in a clay crucible with iron filings and potassium, obtaining a semi-malleable metallic mass which was harder and whiter than iron; and (b) by heating it in a platinum tube in the vapour of potassium. He obtained a pyrophoric dark grey mass containing "small metallic particles which were as soft as potassium, but so small that they could not be more minutely examined, as they melted in boiling naphtha." It is thus very uncertain whether H. Davy succeeded in isolating the metal beryllium. In 1812, F. Stromeyer also claimed to have succeeded in alloying the metal with iron by melting in a closed crucible a mixture of beryllia, carbon, and iron made into a paste with linseed oil. It is doubtful if F. Stromeyer's claim was justified by the results. H. N. Warren claimed to have reduced beryllia in a stream of hydrogen in thin tubes of lime, heated by the oxy-hydrogen flame.

The preparation of beryllium by reduction with metals.—F. Wöhler reduced beryllium chloride with potassium in a platinum crucible, and for the first time obtained the metal, which he called beryllium, as a dark grey powder. Shortly afterwards, and independently, A. A. B. Bussy prepared the metal, which he called glucinum, by a process similar to that employed by F. Wöhler. H. Debray substituted sodium for potassium, and passed the vapour of beryllium chloride over the molten metal; and in 1867, M. Ménier exhibited a sample of beryllium at the Paris Exhibition; he prepared it by the action of sodium on a mixture of beryllium chloride, and the double fluoride of beryllium and potassium, heated in an aluminium crucible. J. E. Reynolds, and L. F. Nilson and O. Pettersson reduced the chloride with sodium; and T. S. Humpidge obtained a metal of 99.2 per cent. purity by this means. J. H. Pollok also produced the metal by reducing the chloride with sodium, but he was unable to fuse together the dark grey powder, because, said he, the metal probably volatilizes without passing through the liquid state. M. A. Hunter heated the chloride in a bomb with sodium. G. Krüss and H. Moraht reduced the double fluoride of beryllium and potassium by sodium, and obtained the metal in hexagonal plates. C. Winkler claimed to have reduced the oxide by magnesium, and H. Goldschmidt, by aluminium, but both methods are unsatisfactory. G. Krüss and H. Moraht used an excess of magnesium and freed the beryllium from magnesium and magnesia by boiling the product for a long time with a soln. of ammonium chloride. K. A. Kühne proposed to use the chlorates or perchlorates in the mixture with H. Goldschmidt's process.

The preparation of beryllium by electrolytic processes.—H. Davy heated an iron wire to whiteness by a battery of 1000 plates, and while negatively electrified fused it in contact with beryllia slightly moistened, and in an atm. of hydrogen gas. He thus obtained an alloy of iron and beryllium. In 1831, A. C. Becquerel thought he had reduced a soln. of beryllium chloride mixed with a little ferric chloride to make it conducting; and, in 1895, H. N. Warren stated that he obtained the metal by the electrolytic reduction of the bromide, with a current of 12 volts and 8 amps.—but the bromide is a non-conductor. In the same year, W. Borchers proposed to

electrolyze a molten mixture of beryllium chloride and an alkali chloride or an alkaline earth chloride. The mixture was made by evaporating a soln. of the two chlorides mixed with a little ammonium chloride to arrest hydrolysis. Calcium and magnesium chlorides should be absent. No statement of the results was made. L. F. Nilson and O. Pettersson electrolyzed a conc. soln. of the chloride with a mercury cathode but obtained no amalgam. P. Lebeau proved that the molten beryllium halides do not conduct electricity, but in the presence of an alkali fluoride, the soln. readily conducts the current; he developed a simple and easy process for producing the metal almost free from foreign admixtures, by electrolyzing the molten double fluoride of beryllium and sodium (or potassium), $\text{BeF}_2 \cdot \text{NaF}$, in a nickel crucible heated over a Bunsen's burner. The salt was made by fusing eq. amounts of the component fluorides. F. Fichter and E. Brunner have emphasized the need for thoroughly dehydrating the mixed fluorides by fusion to a clear glass and removing the scum, before the electrolysis. A current of 6–9 amps. and 35–40 volts was passed and the source of heat removed. The nickel crucible served as negative pole, and a graphite rod as positive pole. During the electrolysis, the heat was maintained just a little above the m.p. of the salt; and the metal was obtained in hexagonal crystals. According to F. Fichter and K. Jablczynsky, if the temp. of the bath rises too high, an alloy of nickel and beryllium is formed. The metal is isolated from the fused mass by dissolving the salts in water, and the soln. is prevented from becoming acid by the addition of ammonia, and the repeated renewal of the water. The crystals of beryllium are freed from admixed oxide by centrifuging in a mixture of ethylene dibromide and alcohol—sp. gr. 1.95. The small crystals so obtained cannot be melted together under ordinary conditions owing to the coating of oxide preventing coalescence; it is necessary to form cylinders by compression, and then heat them up in an electric vacuum furnace, or in one containing hydrogen at 11–15 mm. P. H. M. P. Brinton used a similar process. F. Fichter and E. Brunner used a tungsten tube vacuum furnace. By a similar method of preparation G. Oesterheld obtained a metal with 99.5 per cent. beryllium, and stated that the principal impurity is beryllium carbide. A. Stock and H. Goldschmidt made the compact metal by the electrolysis of a fused bath of an alkaline earth fluoride containing a beryllium compound.

R. Grätzel electrolyzed a molten soln. of the oxide in the chloride of an electropositive metal—say calcium. He assumed that the calcium liberated at the cathode reacted with the beryllia in soln. forming the metal. L. Liebmann reduced a beryllium mineral by electrolysis between metallic electrodes in the presence of fluorine or one of its compounds, either alone or with the addition of a halogen compound of an alkali earth. When a reducing agent, such as carbon, is added to the above mixture, and it is exposed to a white heat, or to that of the electric current, the beryllium carbide developed may, if necessary, be decomposed by suitable admixtures.

Beryllium metal has a dark steel-grey colour, and the crystals have a bright metallic lustre. According to P. Lebeau,² the crystals produced by electrolysis are hexagonal lamellæ, while, according to W. C. Brögger and G. Flink, the hexagonal crystals are holohedral, and are prismatic and tabular, with an axial ratio $a:c = 1:1.5802$. L. W. McKeehan obtained the **X-radiogram** of the hexagonal crystals, which resembles more those of the elements magnesium, zinc, and cadmium, than those of the alkaline earth metals. Here $a = 2.283 \times 10^{-8}$ cms., and $c/a = 1.58$. W. L. Bragg gave 0.115μ for the radius of the at. spheres of beryllium. Beryllium is lighter than aluminium. The **specific gravity** of the crystals produced by electrolysis, according to P. Lebeau, is 1.73 at 15° ; and, according to T. S. Humpidge, those produced by the sodium reduction process have a sp. gr. 1.85 at 20° . F. Fichter and K. Jablczynsky found a sp. gr. 1.842. Several of the early reports of the sp. gr. of the metal referred to impure metal—H. Debray, for example, gave 2.1; L. F. Nilson and O. Pettersson, 1.64; and J. E. Reynolds, 2.0 to 2.13. F. Fichter and K. Jablczynsky say that the regulus of metal has a **hardness** between 6 and 7 on Mohs' scale, and scratches glass at ordinary temp.;

beryllium is brittle, but at a higher temp. it is ductile, and it can be hammered, forged, rolled, and polished.

J. H. Pollok said that in an inert atm. the metal volatilizes without fusion, but L. F. Nilson and O. Pettersson claimed that the metal can be fused under press. Both statements give a wrong impression, for F. Fichter and K. Jablczynsky found that the **melting-point** of the metal is $1280^{\circ} \pm 20^{\circ}$ at ordinary press. ; G. Oesterheld placed the m.p. of the metal at $1278^{\circ} \pm 5^{\circ}$. H. Debray's statement that the metal melts at a lower temp. than silver is therefore wrong. W. Guertler and M. Pirani give 1300° as the best representative value. F. Fichter and E. Brunner added that the metal readily volatilizes at 1530° , under 5 mm. press. in hydrogen. G. Oesterheld made an approximate determination of the **heat of fusion** by comparing the duration of the arrest when equal volumes of gold and beryllium are cooled under similar conditions, and found 271 cal., while Crompton's rule ($\text{At. wt.} \times \text{ht. of fusion} \div \text{absolute temp. of fusion} = 2$) gives a value 341. Beryllium has the largest heat of fusion of any metal, and this corresponds with its high m.p. and low at. wt. The **specific heat** of beryllium has attracted some attention, (i) on account of its value in determining the at. wt. of the element, and (ii) on account of its abnormal value at ordinary temp., as is the case with boron, carbon, and silicon. J. E. Reynolds found the sp. ht. to be 0.642 at 100° ; L. F. Nilson and O. Pettersson calculated the sp. ht. of the pure metal to be between 0.3950 and 0.4005 between 0° and 46.3° ; 0.4242 between 0° and 99.97° ; 0.4750 between 0° and 214.0° ; and 0.5055 between 0° and 299.5° . J. E. Reynolds attributed the difference between his results and those of L. F. Nilson and O. Pettersson to be due to the latter having used crystalline metal while he used amorphous. T. S. Humpidge found the sp. ht. of a specimen with 4.71 per cent. of beryllia, 1.32 per cent. of iron, and a trace of silicon to be 0.4316, from which he calculated the pure metal to have a sp. ht. of 0.4453. Another sample with 99 per cent. of beryllium, 0.43 per cent. beryllia, and 0.57 per cent. of iron, calculated for 100 per cent. beryllium, is

	0°	100°	200°	300°	400°	500°
Sp. ht.	0.3756	0.4702	0.5420	0.5910	0.6172	0.6206

The sp. ht. thus remains practically constant at 0.62, between 400° and 500° , and T. S. Humpidge represents the relation between the sp. ht. and the temp. θ , by the empirical formula $C = 0.3756 + 0.00106\theta - 0.00000114\theta^2$. J. Dewar found 0.0137 for the sp. ht. of beryllium at the temp. of liquid air; and 0.125 for the at. ht. G. N. Lewis and co-workers found the atomic **entropy** at 25° and 1 atm. press. to be 31.8.

R. Thalén³ first studied the **spectrum** of beryllium, and found it to be characterized by lines of equal intensity, one 4572.0 in the blue, and another 4488.5 in the

FIG. 1.—Spectral Lines of Beryllium.

indigo, although R. Bunsen said, in 1876, that neither the spark nor the flame spectrum of beryllium shows any specially characteristic lines. The spectrum of beryllium is poor in lines. W. N. Hartley studied the arc spectrum of the chloride, and found in addition to R. Thalén's two lines, 3320.5, 3130.2, 2649.4, 2493.2, and 2477.7, the second being the strongest and most persistent; he also found that the lines 3130.2 and 2477.7 are still visible in soln. of beryllium salts when the conc. has fallen as low as 0.000001 per cent. H. A. Rowland and R. R. Tatnall found the most prominent lines between 2100 and 4600 to be 2348.697, 2350.855, 2494.532, 2494.960, 2650.414, 2651.042, 3130.556, 3131.200, 3321.218, 3321.486, and 4572.869. R. A. Millikan measured the spectrum in the extreme ultra-violet. According to W. N. Hartley, beryllium oxide is reduced in the oxy-hydrogen flame by a purely chemical process: $\text{BeO} + \text{H}_2 = \text{Be} + \text{H}_2\text{O} - 97.4$

Cals. The oxide is not fusible and not volatile under these conditions, so that the spectrum with the oxy-hydrogen flame is due to the vapour of the metal. C. M. Olmsted studied the band spectrum of beryllium chloride. L. C. Glaser found the structures of the band spectra of beryllium and aluminium are similar. J. Formanek found that when a soln. of the chloride is treated with alkanna tincture it gives a strong orange-red **fluorescence**, and gives three absorption bands. J. L. Soret found soln. of the chloride give no absorption bands, and only a feeble bluish fluorescence. W. Crookes obtained a beautiful blue **phosphorescence**, but no spectral rays, by exposing beryllia to the cathode rays in a vacuum tube. E. Rutherford and J. Chadwick obtained little, if any, evidence of the emission of long-range particles, detected by the scintillations on a zinc sulphide screen, when α -particles pass through beryllium. J. C. McLennan and M. L. Clark found 16.0 and 28.0 for the critical voltages for the L-series of X-rays of wavelength $\lambda = 770.7 \times 10^{-8}$ cms. and 428.1×10^{-8} cms. respectively.

It has been stated that beryllium is a better conductor of electricity than copper or even silver. According to F. Fichter and K. Jablczynsky,⁴ the specific **electrical conductivity** is 5.41×10^4 rec. ohms. When beryllium is used as anode in a soln. of sodium ammonium phosphate, it acts as a rectifier similarly to aluminium. S. Meyer found its **magnetic susceptibility** to be +0.79 at 15°. P. Pascal has found the at. coeff. of magnetization to be -113×10^{-7} units. A. Günther-Schulze studied the **electrolytic valve action** of beryllium in aq. salt soln.

Beryllium is slightly less basic than magnesium. B. Brauner⁵ sums up the chemical nature of this element symbolically by stating that in their chemical properties, $\text{Si} : \text{Be} = \text{Be} : \text{B}$; and $\text{Li} : \text{Na} = \text{Be} : \text{Mg} = \text{B} : \text{Al}$; and $\text{Si} : \text{Mg} = \text{Be} : \text{Al} = \text{B} : \text{Si}$. According to H. Debray, beryllium does not combine directly with **hydrogen**, although C. Winkler thought that he had made some *beryllium hydride* by reducing beryllia with magnesium in an atm. of hydrogen. About 0.33 per cent. of hydrogen was retained by the reduced product. P. Lebeau could not prepare a hydride under these conditions. According to F. Wöhler, beryllium is not oxidized in air at ordinary temp., but when beryllium is ignited in air, it burns vividly, forming a white earth, and in oxygen, it burns very brilliantly, and the resulting oxide shows no signs of fusion; if the metal is contaminated with the hydroxide a flame appears as the metal burns in oxygen, the flame is due to the burning of the hydrogen liberated by the decomposition of the hydroxide. A. A. B. Bussy found that beryllium oxide, BeO , is produced by the oxidation of beryllium heated in an open crucible, but the oxidation is a slow process. Beryllium is said to be as durable as aluminium on exposure to air. According to P. Lebeau, the metal is not altered by exposure to dry **air**, or to **oxygen** at ordinary temp., but if finely divided, it burns if heated *avec un vif éclat*; the temp. of ignition varies with its state of subdivision. The finely divided metal gives brilliant sparks when projected in the flame of a bunsen burner. According to H. Debray, the compact metal does not inflame when heated in oxygen, but becomes covered with a thin protective layer of beryllium oxide, BeO , without further change; F. Wöhler, L. F. Nilson and O. Pettersson, and J. E. Reynolds stated that beryllium is not changed by hot or cold **water**. The apparent inertness of the metal to water is due to a protective film of oxide. The truth is that it is but slowly attacked by cold water, and slowly converted into the hydroxide by boiling water. According to P. Lebeau, beryllium combines easily and directly with **fluorine**, **chlorine**, and **bromine**, and with rather more difficulty with **iodine**; both F. Wöhler and H. Debray noted that combination readily occurs when the metal is heated in iodine vapour. P. Lebeau found that beryllium is violently attacked when the **hydrogen halide** gases are passed over the heated metal; gaseous hydrogen chloride acts on the slightly warmed metal. Practically all the earlier observers—F. Wöhler, etc.—noted that beryllium is readily attacked by dil. **hydrochloric acid**, with the evolution of hydrogen. F. Wöhler stated that when beryllium is heated with **sulphur**, **selenium**, or **tellurium**, the sulphide, selenide, or telluride respectively is formed. F. Wöhler and others noted that the attack by dil. **sul-**

phuric acid resembles that by dil. hydrochloric acid; P. Lebeau found that with conc. sulphuric acid, the metal readily dissolves, and the acid is easily reduced to sulphur dioxide. According to F. Fichter and E. Brunner, beryllium absorbs **nitrogen** when heated above 900° , and a surface layer of beryllium nitride, Be_3N_2 , is formed. The nitride is more easily formed by heating the metal in **ammonia** gas; but is not dissolved by aq. ammonia. F. Wöhler said that the metal he prepared was dissolved by cold dil. **nitric acid** with the evolution of nitric oxide; that of H. Debray dissolved with difficulty in boiling conc. acid; and that of P. Lebeau was only superficially attacked by the conc. acid. According to F. Wöhler, beryllium is attacked when fused with **phosphorus** or **arsenic**, forming respectively the phosphide or arsenide. P. Lebeau found that beryllium unites directly with **carbon** at a high temp., forming beryllium carbide, Be_2C . According to A. Cahours, beryllium replaces the iodine in **methyl iodide** and **ethyl iodide**, forming *beryllium methyl* and *beryllium ethyl*; and, according to V. Lawroff, it also replaces mercury in **mercury methyl** and **mercury propyl**, forming respectively beryllium methyl and *beryllium propyl*. P. Lebeau found that beryllium unites directly with **boron** and **silicon** in the electric arc-furnace. G. Rauter found that when the powdered metal is heated with **silicon tetrachloride** in a sealed tube for 3 hrs. at 240° – 250° , a mixture of beryllium chloride and silicon is formed, together with some beryllium and undecomposed silicon tetrachloride. F. Wöhler and others noted that beryllium is attacked by an aq. soln. of **potassium hydroxide**. A number of alloys of beryllium with other **metals** have been reported—see alloys of beryllium, magnesium, zinc, and cadmium.

C. L. Parsons⁶ has emphasized what he called “the vagaries of beryllium,” meaning “those peculiarities of the element which stand out prominently as characteristic of itself.” It has been said, probably with truth, that the literature of inorganic chemistry is overburdened with compounds which have no actual existence, but which have obtained their place and been assigned formulæ simply from the analysis of solid phases—mixed crystals, residues of evaporation, indefinite gummy precipitates, etc.—obtained under variable conditions and without other attempt to prove their individuality, and C. L. Parsons claims that the beryllium compounds are a striking illustration. The halides of beryllium—excepting perhaps the fluorides—are immediately hydrolyzed in contact with water; they are even more sensitive than the corresponding salts of aluminium. By careful manipulation of the evaporation residues, substances of almost any degree of basicity can be prepared. These are possibly all mixtures of base with the normal salt; but analyses have given rise to claims for numerous oxyfluorides and oxychlorides. Few normal salts of the non-volatile acids have been made. The sulphate, selenate, and oxalate form aq. soln., which approach soln. of the acids themselves in attacking the metals or carbonates, liberating hydrogen or carbon dioxide respectively, and reddening blue litmus. The soln. of the salts dissolve large quantities of the hydroxide, and even then the soln. attack metals and the carbonates vigorously. The normal salts of the volatile acids—carbonates, sulphites, and nitrites—cannot be made in aq. soln., but many are prepared by direct union of the oxides, or by precipitation from alcoholic soln. The normal borates, iodates, chlorates, bromates, phosphates, chromates, and acetates have not been obtained. Many basic salts have been obtained by heating conc. soln. of the hydroxide in the normal salt soln. along with beryllium carbonate. The basic precipitates are probably solid soln. of variable composition. The action of water on the compounds of beryllium is greatly modified, as is the case with magnesium, aluminium, etc., by the entrance of another element into the molecule. Hence, many double salts have been crystallized from aq. soln. in well-defined crystals under conditions where the normal salt could either not be obtained at all, or obtained only with difficulty—e.g. the double carbonates, chlorides, nitrates, sulphites, and iodides.

The soln. of the hydroxide in the normal sulphate, nitrate, or chloride are less hydrolyzed than the corresponding salts of aluminium and iron; while the hydroxide

can be partially removed by dialysis into water, there is little evidence of a colloidal soln. There are no signs of the formation of complex salts. This is supposed to be a case of the simple soln. of a substance (beryllium hydroxide) in a mixed solvent (water and normal salt) in one of which alone (water) it is insoluble; for the solid, when once dissolved, acts as a solvent for its own oxide or hydroxide.

Reactions of analytical interest.—The reactions of beryllium salts are in many respects like those of aluminium; they do not give precipitates in the hydrochloric acid or hydrogen sulphide groups, but, as T. J. Pelouze⁷ has shown, a mixture of ammonium hydroxide and **ammonium sulphide** gives a white precipitate of beryllium hydroxide, $\text{Be}(\text{OH})_2$, similar to that of aluminium hydroxide; hydrogen sulphide is at the same time evolved, and the precipitate is insoluble in an excess of the precipitant, but readily soluble in hydrochloric acid, forming a yellow soln. whose colour disappears on dilution. Similar results are obtained with aq. soln. of the **alkali sulphides**. A soln. of **potassium hydroxide**—or of sodium hydroxide—gives a gelatinous precipitate of beryllium hydroxide readily soluble in an excess of the reagent, but not in aq. ammonia: $\text{Be}(\text{OH})_2 + 2\text{KOH} \rightleftharpoons \text{Be}(\text{OK})_2 + 2\text{H}_2\text{O}$. Unlike the corresponding soln. with aluminium hydroxide, the soln. is decomposed hydrolytically on boiling, and the beryllium is re-precipitated as hydroxide provided a great excess of the alkali hydroxide be not present. This enables the two hydroxides to be separated, but to make the separation complete, the precipitate should be redissolved and reprecipitated several times. According to F. Toczyknsky, tartaric acid hinders the precipitation by alkali hydroxides; cane sugar, grape sugar, and glycerol act similarly to a smaller degree; the precipitate with baryta-water also dissolves in an excess of the precipitant, but, as L. N. Vauquelin showed, the soln. remains clear on boiling. According to C. G. Gmelin, and F. Schaffgotsch, both beryllium and aluminium hydroxides are reprecipitated from the soln. in caustic lye by the addition of **ammonium chloride**. According to C. Vincent, and C. Renz, **methylamine** or **ethylamine** precipitates beryllium hydroxide, and, unlike aluminium, but not unlike iron, the precipitate is not soluble in an excess of the precipitant. A soln. of **ammonium carbonate** produces a white precipitate of a basic beryllium carbonate, which, unlike the corresponding precipitate with aluminium, is readily soluble in an excess of the reagent. When the soln. is boiled, the basic carbonate is reprecipitated. This property enables the two compounds to be separated, but the separation is quantitative only when the carbonate is redissolved and reprecipitated a number of times. According to L. N. Vauquelin, and C. G. Gmelin, soln. of the **alkali carbonates** also precipitate basic beryllium carbonate, soluble only in a large excess of the sodium or potassium carbonate, and in a far smaller excess of ammonium carbonate. When the soln. of the beryllium hydroxide in alkali carbonates is boiled, a partial precipitation of beryllium as hydroxide occurs only when the soln. is much diluted. The solubility of the hydroxide and carbonate precipitates decreases with increasing age of the precipitate. If a mixed soln. of a beryllium and an aluminium salt with 10 per cent. of sodium hydrocarbonate be boiled, aluminium, but not beryllium, hydroxide is precipitated. **C. L. Parsons' test** for beryllium is as follows:

Follow the customary procedure of qualitative analysis until the sulphides insoluble in HCl have been removed. Concentrate the filtrate so obtained to 25 cubic centimetres and when cold add two grams solid Na_2O_2 , boil and filter. Acidify the filtrate with HNO_3 and add ammonia in excess. If no precipitate is obtained beryllium is absent. Wash any precipitate formed and add it together with two to three grams solid NaHCO_3 to 30 cubic centimetres (10 per cent. soln.) of water in a test-tube or casserole and bring rapidly to boiling. Boil for one-half minute only and filter to remove all aluminium. Dilute the filtrate with 10 volumes of water (1 per cent. soln.) and boil. Beryllium hydroxide containing a little carbonate will precipitate if present. Other elements do not interfere.

According to A. von Awdejef, J. Weeren, H. Rose, J. M. Ordway, H. J. Debray, and F. von Kobell, when a cold soln. of a beryllium salt is digested with **barium carbonate**, beryllium hydroxide is partially precipitated in the cold, completely on

boiling. F. von Kobell stated that **calcium carbonate** does not precipitate beryllium hydroxide in the cold, but does so on boiling. Unlike thorium, zirconium, erbium, yttrium, cerium, lanthanum, or didymium salts, **oxalic acid** and **ammonium oxalate** give no precipitation with beryllium salts; but with conc. soln. of beryllium salts, potassium hydro-oxalate precipitates potassium beryllium oxalate. Unlike cerium, lanthanum, or didymium salts, **potassium sulphate** gives a fine crystalline precipitate, $\text{Be}(\text{KSO}_4)_2 \cdot 2\text{H}_2\text{O}$, which is soluble in a conc. soln. of potassium sulphate. A soln. of **sodium phosphate** in presence of ammonium phosphate gives a white precipitate with beryllium salts. According to C. Rössler, an excess of a soln. of **diammonium hydrophosphate**, not disodium hydrophosphate, gives a precipitate with a beryllium salt which, when dissolved in hydrochloric acid, and the soln. just neutralized with ammonia, and boiled, gives a crystalline precipitate. The precipitation is not hindered by citric acid, while small amounts of aluminium are not precipitated; if much aluminium is present, the presence of citric acid hinders the precipitation of the beryllium ammonium phosphate. When a beryllium salt is fused with **potassium hydrofluoride**, and the cold mass extracted with water acidified with hydrofluoric acid, the beryllium fluoride dissolves, while aluminium forms a sparingly soluble potassium aluminium fluoride. According to C. A. Joy, a soln. of **sodium thiosulphate** gives a precipitate when boiled with a soln. of beryllium chloride. According to J. F. Persoz, C. A. Joy, and F. Toczyksky, a soln. of a beryllium salt gives a precipitate when boiled with **sodium acetate**; C. G. Gmelin said the chloride is not so precipitated. L. N. Vauquelin obtained a white precipitate with **alkali succinate**, and yellow flecks with **tincture of galls**. H. Rose obtained a kind of jelly by adding **potassium ferrocyanide** to a soln. of a beryllium salt. According to J. J. Berzelius, no precipitate is given by **potassium ferricyanide**, **hydrofluosilicic acid**, oxalic acid, **potassium oxalate**, or **potassium tartrate**. Beryllium chloride soln. becomes dark in colour, but no precipitation occurs with **potassium thio-carbonate**, K_2CS_3 . When calcined with a soln. of **cobalt nitrate**, beryllia gives a grey mass; with alumina, Thénard's blue is formed. According to A. C. Neisch, **metanitrobenzoic acid** gives no precipitate with a beryllium salt. C. L. Parsons' sodium hydrocarbonate process, and F. S. Havens' hydrogen-chloride process, previously discussed in connection with the preparation of beryllia, are recommended as quantitative processes.

Uses.—According to C. James,⁸ beryllium oxide “is used in the manufacture of incandescent mantles in order to make them stronger. The amount used depends upon the manufacturer. Some makers use 5 grms. of beryllium nitrate to every kilogram of thorium nitrate, while others use only 2 grms. to the same quantity of thorium salt. Beryllium salts are useful in the manufacture of incandescent mantles. The oxide is sometimes added to material that is being used for the manufacture of abrasives.” The metal has some valuable qualities, and it is said that “only the expense of production prevents the metal proving of great industrial value.”

§ 4. The Atomic Weight and Valency of Beryllium

The valency of beryllium was for many years a subject of controversy, and it incited much research. It can be argued that the element is bi- or ter-valent, although it is now generally agreed to regard it as a bivalent element. The hydrogen eq. of beryllium is nearly 4.5; if the at. wt. of beryllium is nearly 9, the element is bivalent, if 13.5, trivalent, and if 18, quadrivalent. J. J. Berzelius¹ at first regarded

beryllium as a bi- or quadri-valent element, for he formulated the oxide as either BeO or BeO_2 , but in 1815, from its analogies with alumina, he considered beryllium to be trivalent, and the oxide to have a formula either BeO_3 or Be_2O_3 . The specific heat law of Dulong and Petit, and the isomorphism law of Mitscherlich, seemed to favour this assumption. Thus, according to P. Hautefeuille and A. Perrey, beryllium can replace aluminium in silicates of the type $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$.

Beryllium occupies rather a unique position in the magnesium-zinc family group of the periodic table. It does not share with the magnesium, zinc, and cadmium salts their characteristic behaviour towards ammonia and the ammonium salts; their tendency to form double salts with other metals; the sparing solubility of their oxides in water, and their solubility in weak acids. Nor does it share the characteristics of calcium, strontium, and barium in forming soluble strongly alkaline hydroxides, sparingly soluble sulphates, soluble sulphides, and slightly soluble fluorides. In fact, beryllium is so like aluminium that until its at. wt. and the vapour density of its chloride had been determined, it was regarded as a triad element related to aluminium. A. von Awdejoff favoured the hypothesis that beryllium is bivalent, owing to the close analogy of potassium beryllium sulphate and potassium beryllium fluoride with the corresponding magnesium salts; similar remarks apply to C. Scheffer's observations on beryllium phosphate.

G. Wyruboff further emphasized the possible trivalency of beryllium from the analogies between the beryllium silico-tungstates and the corresponding aluminium salt; J. Blake also argued in the same direction from the likeness in the physiological action of beryllium and aluminium; P. Lebeau showed that the properties of the carbides of the two elements favour the trivalency of beryllium. H. Traube's determinations of the at. soln. vol. of beryllium sulphate and chlorate are more in accord with a trivalent beryllium than with a bivalent element. Some early determinations of the sp. ht. of beryllium favoured the trivalency hypothesis, but the data were by no means unequivocal because (i) the results were discordant owing to the use of impure metal, (ii) the sp. ht. varies very much with the temp., and (iii) the elements with a low at. wt. often deviate so much from Dulong and Petit's rule that the application of the rule is not of much value as a criterion. The question was discussed by J. E. Reynolds, L. Meyer, L. F. Nilson and O. Pettersson, etc. T. S. Humpidge showed that at a high temp. when the sp. ht. becomes approximately constant, the application of Dulong and Petit's rule favours the bivalency of the element. G. Tammann showed that the vapour density determinations of aq. soln. of beryllium salts do not give a definite value for the mol. wt. H. Ley found the electrical conductivity of normal soln. of beryllium sulphate furnishes $\lambda_{32} - \lambda_{1024} = 54.2$, and has shown that although this agrees with the value for the salts of the trivalent elements, it would be wrong to assume that beryllium is trivalent because the great increase in the eq. conductivity can be explained by the hydrolysis of the salt.

The most cogent argument in favour of the bivalency of beryllium was the results of the determination of the vapour density of the chloride. The earlier observations were affected by errors through the decomposition of the salt by moist air, and not to the dissociation of the chloride. The decomposition does not occur if the salt is volatilized in a stream of hydrogen chloride or carbon dioxide. L. F. Nilson and O. Pettersson found (air unity):

	589°	597°	604°	686°	720°	745°	812°
Vap. density . . .	3.067	3.031	3.090	2.853	2.926	2.753	2.793

when the calculated value for BeCl_2 is 2.77. Above 1000° , the results were quite constant for BeCl_2 . T. S. Humpidge found 2.733 and 2.714 respectively at 635° and 785° . These results are all entirely in accord with the bivalency of beryllium, and they were confirmed by observations on the vap. density of beryllium bromide by T. S. Humpidge; of beryllium acetylacetonate, $\text{Be}(\text{C}_5\text{H}_7\text{O}_2)_2$, by A. Combes; and of basic beryllium acetate, $\text{Be}_4\text{O}(\text{CH}_3\text{COO})_2$, by G. Urbain and H. Lacombe.

S. Tanatar, however, expressed the belief that G. Urbain and H. Lacombe's compound contained two quadrivalent beryllium atoms per molecule, and not four bivalent beryllium atoms, in order to explain its constitution. This he supposes to be $R_3Be^{IV}-O-OB^{IV}R_3$. It would, however, be legitimate to raise the question whether or not the alleged basic acetate is a chemical individual. It must also be remembered that the association of the molecules plays an important part in these determinations, for W. Biltz found the acetylacetonates of the rare earths are bimolecular in conc. soln. The mol. wt. determinations of beryllium picrate, $Be(C_6H_2O_7N_3)_2 \cdot 3H_2O$, from the f.p. of its acetophenone soln., by B. Glassmann, and of that of beryllium chloride from the b.p. of its pyridine soln. by A. Rosenheim and P. Woge, are all in agreement with the bivalency of beryllium. The latter also found that the compounds of beryllium with the oxalates are quite different from those which it forms with the trivalent metals chromium, iron, or aluminium.

T. Carnelley pointed out that his determinations of the m.p. and b.p. of beryllium bromide or chloride better fitted a place in the periodic table with a bivalent than with a trivalent element; and B. Brauner made a similar observation with respect to the mol. vol. of beryllium compounds. W. N. Hartley also showed that the spectrum of beryllium corresponds with the first member of a dyad series in which calcium, strontium, and barium are homologues. L. Meyer also showed that beryllium better fits a place among the bivalent elements in the periodic table, than among the trivalent elements. D. I. Mendeléeff found that the soln. of a mol of the chloride of a metal MCl_n in 200 mols of water gives a soln. whose sp. gr. increased proportionally with the mol. wt. of the solute. If the molecule of beryllium chloride be $BeCl_2$, mol. wt. 80, it must be heavier than the molecule of potassium chloride, KCl , mol. wt. 74.5, and less than the molecule of magnesium chloride, $MgCl_2$, mol. wt. 95. On the other hand, if beryllium chloride be $BeCl_3$, mol. wt. 120, its molecule must be heavier than that of calcium chloride, mol. wt. 111, and lighter than manganese chloride, $MnCl_2$, mol. wt. 126. Experiment showed the correctness of the former assumption—at $15^\circ/4^\circ$, the soln. $BeCl_2 + 200H_2O$ has a sp. gr. 1.0138; thus being greater than the sp. gr. of the soln. $KCl + 200H_2O$, 1.0121, and less than that of the soln. $MgCl_2 + 200H_2O$, 1.0203. Hence, said he, "the bivalency of beryllium is confirmed by the dissolved and vaporized chloride."

J. J. Berzelius' determination² of the at. wt. of beryllium is little more than an approximation, and is of only historical interest. He determined the ratio of beryllium to chlorine in beryllium chloride, and the ratio of beryllium oxide to sulphur trioxide in beryllium sulphate, and his number, recalculated for $O=16$ is $Be\ 10.6$. A. von Awdejef (1842) analyzed the sulphate, and from the ratio $BeO : BeSO_4$ computed $Be=9.337$; J. Weeren (1854) in the same way obtained 9.267 and G. Klatzo (1869), 9.283. H. Debray (1855) analyzed beryllium oxalate, and determined the ratio $4CO_2 : BeO$, from which he calculated the at. wt. $Be=9.337$. L. F. Nilson and O. Pettersson (1880) analyzed the hydrated sulphate and determined the ratio $BeSO_4 \cdot 4H_2O : BeO$, from which they calculated the at. wt. $Be=9.113$; and G. Krüss and H. Moraht similarly obtained $Be=9.062$. C. L. Parsons (1904) determined the ratio $Be_4O(C_2H_3O_2)_6 : BeO$, and hence calculated the at. wt. $Be=9.106$ and also $Be(C_5H_7O_2)_2 : BeO$, and hence computed $Be=9.103$. From these results F. W. Clarke and B. Brauner have computed that the best representative value for the at. wt. of beryllium is $Be=9.1$, and this, too, is the value in the International Table (1920). L. Benoist and H. Copaux infer that beryllium has an at. wt. 9.1 from a comparison of the transparency of the oxide to X-rays, with the transparencies of aluminium, sulphur, carbon, lithium, and lithium hydroxide. From the ratios $BeCl_2 : 2Ag$, and $BeCl_2 : 2AgCl$, O. Hönigsmid and L. Birckenbach computed 9.018 as the best representative value. The **atomic number** is 4. According to G. P. Thomson, the anode ray analysis of beryllium corresponds with an at. wt. 9.0 ± 0.1 ($Na=23$), and no **isotopes**. No indication was found which would suggest that the atom of beryllium can lose two electrons under the conditions of the experiments.

G. Krüss and H. Moraht³ noted the presence of a foreign substance in their ammonium carbonate soln. of beryllium hydroxide, which gave a black sulphide and a white hydroxide, implying the presence of a new element. C. L. Parsons showed that G. Krüss and H. Moraht's precipitate was probably a mixture of zinc and iron sulphides, but mainly zinc. J. H. Pollok found the precipitate contained zinc, iron, nickel, and another unknown substance. This latter he claimed to be a new element accompanying ordinary beryllium in considerable quantities because in a single fractional sublimation of the chloride in a porcelain tube, he obtained over 0.4 grm. of a chloride, which, on analysis, gave an at. wt. as high as 37; he also claimed that by a single recrystallization of the sulphate, he obtained an increase in the eq. of the metal in the first crop of crystals above the second crop. C. L. Parsons showed that J. H. Pollok's results are to be explained by the special tendency of beryllium chloride to decompose when exposed to the action of moisture, and that the access of moist air to the chloride results in a loss of chlorine. L. F. Nilson and O. Pettersson also obtained results resembling those of J. H. Pollok, and therefore took special precautions against moisture in their experiments on the vap. density of the chloride.

§ 5. Beryllium or Glucinum Oxide

Beryllium oxide is the product of the oxidation of the metal when heated in air or oxygen. The extraction of beryllium oxide or carbonate from beryl and other minerals has already been described. The beryllium oxide, BeO, or *beryllia*, is prepared by calcining a salt of beryllium containing a volatile acid radicle—e.g. the nitrate, sulphate, oxalate, hydroxide, basic carbonate, etc.—even the chloride, bromide, or iodide yield practically all their metal as oxide when evaporated from soln., and heated; if a mixed soln. of beryllium and ammonium chlorides be so treated, a light feathery oxide is obtained which is difficult to retain in the containing vessel. J. J. Ebelmen¹ obtained it in the form of hexagonal crystals by heating beryllium silicate with an excess of potassium carbonate; and H. Debray, by strongly heating beryllium sulphate, or ammonium beryllium carbonate. P. Hautefeuille and A. Perrey obtained crystals of beryllia by fusing the oxide with beryllium

leucite; or the sulphate with silicic acid; or by fusing beryllium oxide with alkali sulphides at dull redness. The form of the crystals at high temp. is different according as potassium sulphide, sodium sulphide, or a mixture of alkali sulphide and sodium carbonate is employed. H. Grandeau heated beryllium pyrophosphate with a great excess of potassium sulphate between 1400° and 1500° , and extracted the mass with water, when there remained fine crystals of beryllia. P. Lebeau observed crystals, probably produced by sublimation, on the surface of beryllium oxide which had been melted in the electric arc-furnace.

Beryllium oxide as ordinarily prepared is a white powder. M. Levi-Malvano claimed that a blue-coloured oxide is obtained by the ignition of the hexahydrated sulphate; the colouring agent is probably some impurity, because C. L. Parsons could not verify the result. According to E. Mallard, the **crystals** belong to the hexagonal system, and have axial ratios $a:c=1:1.6305$; they are isomorphous with those of magnesium oxide; while, according to J. J. Ebelmen, the crystals are isomorphous with alumina. W. L. Bragg estimates that the **X-radiogram** will give the zinc oxide lattice with atoms 1.78 A. apart; W. Gerlach obtained 3.796 ± 0.00 A. for the length of the edge of the elementary cube. The cubic lattice is of the sodium chloride type. It was investigated by L. W. McKeehan, who found $a=2.696 \times 10^{-8}$ cms. and $c/a=1.63$.

The **specific gravity** of beryllium oxide, unlike that of alumina, does not change sensibly by ignition, and there are no signs of polymerization. For example, P. Lebeau found at 0° for beryllia calcined at about 400° , 3.012 ; calcined about 1000° , 3.010 ; crystallized by volatilization, 3.015 ; and fused beryllia, 3.025 . H. Rose found the sp. gr. of the powder to be 3.083 to 3.090 ; that precipitated and ignited in the alcohol flame, 3.090 to 3.096 at 12° ; that ignited in the pottery oven, 3.201 to 3.027 (10°), and that of the crystalline oxide 3.021 (9°), so that with H. Rose the sp. gr. is less with the higher temp. of calcination. A. G. Ekeberg gave 2.967 for the sp. gr. of amorphous beryllia; G. Krüss and H. Moraht, 2.9644 (10.5°); J. J. Ebelmen, 3.02 – 3.06 for crystalline beryllia; L. F. Nilson and O. Pettersson, 3.016 ; H. Grandeau, 3.18 (14°). According to J. J. Ebelmen, the crystals of beryllia scratch quartz but not ruby, and, according to P. Lebeau, the **hardness** of the crystals from the electric arc-furnace is nearly that of corundum.

H. Davy said that beryllia neither hardens nor shrinks when heated, and fuses only at the highest temp. that can be produced. H. Caron² found beryllia to be infusible in the oxy-hydrogen blowpipe flame, but it volatilizes before that temp. is attained, and P. Lebeau found that the oxide can be fused and distilled in the electric arc-furnace. According to F. Fichter and E. Brunner, beryllia has a **melting-point** $2450^{\circ} \pm 50^{\circ}$, but is very volatile near that temp. O. Ruff, H. Seifert, and J. Suda gave 2525° for the m.p. of beryllia, and also found it volatilized below the m.p. E. Tiede and E. Birnbräuer said that beryllia melts at $2400^{\circ} \pm 100^{\circ}$, in a vacuum furnace, and that it does not volatilize much below the m.p. W. R. Mott gave 3900° for the **boiling-point** of beryllium oxide, and he added that this oxide is left as a residue by the distillation of its mixtures with the oxides of calcium, barium, strontium, magnesium, aluminium, and silicon. L. F. Nilson and O. Pettersson found the **specific heat** of the oxide to be 0.247 between 0° and 100° . According to S. Tanatar, the sp. ht. of the oxide at 100° – 117° is 0.2898 , and he calculated therefrom an abnormally low sp. ht. for the metal, and thence argued that beryllium is quadrivalent, exactly as the low sp. ht. of the element was previously used as an argument for the tervalency of the metal. H. Copaux and C. Philips gave for heat of oxidation $\text{Be} + \text{O}_{\text{gas}} = \text{BeO} + 151.5$ cal.; and W. Mielenz and H. von Wartenberg, 135.9 ± 0.9 Cals.

According to E. Mallard,³ the **index of refraction** for the ordinary ray is 1.719 , and for the extraordinary ray 1.733 ; and the double refraction is positive. H. E. Ives and co-workers studied the illuminating power and emissivity of beryllia when made into mantles and heated by Bunsen's flame. W. Crookes found that when exposed to the **cathode rays** in a vacuum tube, beryllia gives a beautiful blue **phos-**

phorescence, but no spectral rays ; it shows only a conc. of light in the blue. There is no residual glow. L. Benoist and H. Copaux studied the **X-ray** transparency of the oxide. E. F. Nichols found that when heated to 1000° in the oxyhydrogen flame, beryllia appears blue, not red. According to L. F. Nilson and O. Pettersson, beryllia is diamagnetic ; but S. Meyer found its **magnetic susceptibility** to be zero at 16°.

According to P. Lebeau,⁴ the chemical activity of beryllium oxide is dependent on the temp. at which it has been calcined. According to J. J. Berzelius, beryllia after ignition dissolves much more slowly in acids, and the affinity of beryllium oxide for the acids is less powerful than that of magnesia or yttria. The oxide is not reduced when heated in a stream of **hydrogen** ; nor is it attacked by **water**. R. Haas did not succeed in making *beryllium peroxide* by treating beryllium oxide with **hydrogen peroxide**, according to L. J. Thénard's process for zinc peroxide. The oxide was found by P. Lebeau to be attacked by **fluorine** with the formation of a fluoride. A. G. Balard stated that beryllium oxide is attacked by bromine water, especially under the influence of sunlight ; but P. Lebeau found that the oxide calcined at 440° is inert towards **chlorine**, **bromine**, or **iodine** ; nor do the **hydrogen halides** attack the oxide at a red heat. Conc. **hydrochloric acid** dissolves the oxide slowly, and faster if the acid be boiled, and the oxide be finely divided. A mixture of the oxide with carbon is attacked, forming the halide, when heated in a stream of a hydrogen halide. L. Meyer found the anhydrous chloride is formed when the oxide is heated in a stream of **carbon tetrachloride** vapour ; and F. Bourion found that the chloride is similarly formed when the oxide is heated to redness in a stream of **sulphur chloride** vapour. L. N. Vauquelin found that beryllium oxide is not changed when heated with **sulphur**. Conc. **sulphuric acid** readily attacks the oxide, forming the anhydrous sulphate, which, according to P. Lebeau, dissolves but slowly when the mixture is diluted with water, owing to the gradual hydration of the salt. According to P. Lebeau, beryllium oxide is reduced at a high temp. by **carbon**, forming the carbide—E. Tiede and E. Birnbrauer said the reduction begins at about 2400°. P. Lebeau also found that beryllia is reduced by **boron** forming the boride, and by **silicon** forming the silicide. The oxide is not acted on by **carbon dioxide** ; and, according to E. Frémy, the vapour of **carbon disulphide** does not convert the heated oxide into sulphide. Beryllium oxide is dissolved more slowly by conc. **nitric acid** than by conc. hydrochloric acid. H. Rose found that beryllia partially decomposes soln. of **ammonium chloride**, but the beryllia loses this property if pre-calcined ; he also found that the oxide is only partially decomposed by heating it with ammonium chloride. According to P. Lebeau, beryllia is not reduced by **potassium**, **sodium**, **magnesium**, or **aluminium**—*vide* beryllium hydride—and L. Franck found that aluminium forms an alloy when heated to a high temp. with beryllium oxide ; it is also reduced by carbon in the presence of other metals, like copper, with which the beryllium forms alloys. K. A. Hofmann and K. Hörschle found that beryllium oxide fused with **magnesium chloride** furnishes volatile beryllium chloride. According to H. Debray, fused **potassium hydroxide** readily dissolves beryllium oxide, and, according to C. A. Joy, the molten mass is soluble in water. J. Weeren, and A. Atterberg stated that water does not dissolve the beryllia. C. G. Gmelin, and H. Debray also stated that beryllia is not soluble in an aq. soln. of potassium hydroxide. According to J. J. Ebelmen, beryllia is readily dissolved by fused **potassium hydrosulphate**.

§ 6. Beryllium or Glucinum Hydroxides

According to C. L. Parsons, beryllium hydroxide, $\text{Be}(\text{OH})_2$, is one of the most interesting compounds of beryllium. As previously indicated in connection with the reactions of beryllium salts, beryllium hydroxide is precipitated from soln. of beryllium salts by aq. ammonia, ammonium sulphide, alkali hydroxides, barium carbonate, methylamine or dimethylamine, and ethylamine or diethylamine. Soln. of normal carbonates precipitate a mixture of basic beryllium carbonate and the hydroxide; the former can be almost entirely eliminated by boiling the mixture. According to J. Weeren,¹ and A. Atterberg, the normal hydroxide, $\text{Be}(\text{OH})_2$, is precipitated by boiling a soln. of beryllium oxide in potassium hydroxide and by digesting with water the product of fusing beryllia with potassium hydroxide. C. L. Parsons, W. O. Robinson and C. T. Fuller obtained beryllium hydroxide of a high degree of purity, by dissolving impure beryllium hydroxide in a soln. of ammonium carbonate, and precipitating the basic carbonate with steam. The precipitate is washed with hot water, and boiled with water, while a stream of air was passed through the liquid. The water is frequently renewed, and the product then contains very little ammonia or carbon dioxide.

J. M. van Bemmelen distinguished two forms of the hydroxide, the one, which he called the α -beryllium hydroxide, is granular, and the other, the β -beryllium hydroxide, is gelatinous. The β -hydroxide is precipitated by ammonia from a soln. of beryllium sulphate; it is washed with cold water out of contact with air; dried in a stream of air freed from carbon dioxide, and powdered. Its composition approximates to $\text{BeO} \cdot 1.61\text{H}_2\text{O} \cdot 0.025\text{CO}_2$, and when washed and dried in air, $\text{BeO} \cdot 2.63\text{H}_2\text{O} \cdot 0.05\text{CO}_2$, but it has not a constant composition. The α -hydroxide is prepared by precipitation from alkaline soln. of the oxide. A soln. of the β -hydroxide in sulphuric acid is precipitated by potassium hydroxide, and redissolved by an excess of the alkali. The soln. is then diluted with water and boiled. The granular deposit is then washed with hot water, while air is excluded. It is a fine white crypto-crystalline powder, is free from carbon dioxide, and has the composition

$\text{BeO} \cdot \text{H}_2\text{O}$. In general, J. M. van Bemmelen concludes that α -beryllium hydroxide is a chemical individual of definite composition, $\text{Be}(\text{OH})_2$, like the hydroxides of calcium or magnesium, while β -beryllium hydroxide is of indefinite composition and behaves like the gelatinous aluminium and ferric hydroxides; it may therefore be regarded as **colloidal beryllium oxide**, for there is little to show that the water is other than adsorbed or mechanically held. This explains A. Atterberg's claim to have prepared a number of hydrated beryllium hydroxides— $\text{Be}(\text{OH})_2 \cdot \frac{1}{3}\text{H}_2\text{O}$; and $\text{Be}(\text{OH})_2 \cdot 2\frac{1}{3}\text{H}_2\text{O}$. These may be regarded as different stages in the desiccation of colloidal, or β -beryllium hydroxide.

J. M. van Bemmelen measured the water content of the crystalline and colloidal forms of the hydroxide, $\text{BeO} + n\text{H}_2\text{O}$, dried over conc. sulphuric acid and then heated to different temp.

$n\text{H}_2\text{O}$		15°	50°	75°	100°	125°	150°	180°	200°	212°
	(Crystalline	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	0.95
	(Colloidal .	1.47	1.40	1.29	1.18	1.08 (14)	1.12 (11)	1.0	1.0	—

The numbers in brackets refer to the time, in hours, the hydrate was heated. The composition of the colloidal form gradually and constantly changes owing to the loss of water with a progressively rising temp., and to the passage of the colloidal or β -form into the crystalline α -form between 150° and 180°. The composition of the crystalline or α -form remains constant with a progressively rising temp., and it begins to dissociate just over 200°; and at higher temp. he finds:

$n\text{H}_2\text{O}$		220°	235°	250°	280°	Red heat.
	(Crystalline	0.18	0.16	0.14	0.13	0.00
	(Colloidal .	0.50	0.45	0.42	0.36	0.00

Crystalline, or α -beryllium hydroxide absorbs as much as 0.25 to $0.5\text{H}_2\text{O}$ from air sat. with moisture, but the absorbed water is given up again in dry air; after losing $\frac{1}{2}\text{H}_2\text{O}$ near 200°, the constitution is definitely changed, for it absorbs a mol of H_2O from moist air at 15°, but gives it up again in dry air; after heating to 280°, the water of the crystalline hydroxide is reduced to $0.13\text{H}_2\text{O}$, and it again absorbs a mol of water at 15°, but gives it up again in dry air only till the residue is reduced to $0.18\text{H}_2\text{O}$; and after heating to redness it behaves in the same way, but a strong red heat changes it altogether, for it then loses all power of absorbing water. When the colloidal or β -hydroxide has been heated to about 215°, it undergoes changes similar to the α -hydroxide. The changes which the β -compound undergoes during heating are like those observed by M. Berthelot with ferric hydroxide, for he found that from the time when it was precipitated, it constantly changed, and at no period could be represented by a single formula. J. M. van Bemmelen attributed this behaviour of the colloidal hydroxide to its being a mixture of hydroxides which behave differently at the same temp., that is, each one requires a different temp. to convert it into the lower hydroxide or anhydride.

When a soln. of beryllium sulphate is dropped into one of potassium hydroxide, a saturation point is reached depending on the conc. of the hydroxide. The beryllium hydroxide in soln. is considered by B. Bleyer and S. W. Kaufmann to be an unstable *A*-form; the hydroxide which separates from this soln. is in the *B*-form; and when the *B*-form is dried it passes into a third *C*-form. The solubilities of these three modifications of beryllium hydroxide in soln. of potassium hydroxide of different conc., are shown in the curves, Fig. 2, and expressing conc. in mols per litre, at 18°:

	<i>A</i> -form.			<i>B</i> -form.			<i>C</i> -form.		
KOH . . .	0.90	2.02	2.90	0.49	2.07	2.69	1.0	2.5	3.5
BeO . . .	0.100	0.3273	0.5140	0.0196	0.0809	0.1071	0.0139	0.0518	0.0943

Analyses after washing show that the *A*-form is $\text{H}_2\text{Be}_2\text{O}_3$; while the *B*- and *C*-forms are H_2BeO_2 . The ionic constants of the *A*-, *B*-, and *C*-forms are respectively $k_1 = 0.73 \times 10^{-29}$; $k_2 = 0.28 \times 10^{-29}$; and $k_3 = 0.144 \times 10^{-29}$; and the constants of

the acid dissociation, respectively 1.5×10^{-12} , 0.56×10^{-12} , and 0.29×10^{-12} . Freshly prepared beryllium hydroxide is a somewhat stronger acid than zinc hydroxide in the corresponding state.

J. Thomsen found the **heat of neutralization** of beryllium hydroxide to be $\text{Be}(\text{OH})_2 + \text{H}_2\text{SO}_4 + \text{Aq.} = 16.1$ Cals.; $\text{Be}(\text{OH})_2 + 2\text{HCl} + \text{Aq.} = 13.64$ Cals.; and E. Petersen, $\text{Be}(\text{OH})_2 + 2\text{HF} + \text{Aq.} = 19.683$ Cals. J. K. Wood found that the weak beryllium hydroxide has the dissociation constant, $K = 5.2 \times 10^{-11}$. S. Glixelli measured the **electro-osmosis** of beryllium hydroxide. S. Meyer found the **magnetic susceptibility** of the hydroxide to be zero at 16° . P. Pascal found the mol. coeff. of magnetization to be -82×10^{-7} units.

The properties of beryllium hydroxide vary greatly with its mode of preparation. Conc. soln. of one eq. of the normal salts can dissolve two to five eq. of the hydroxide—e.g. the oxalate or the sulphate dissolves nearly 3 eq., the chloride, 4 eq., and the acetate nearly 6 eq.—and the hydroxide is reprecipitated by dilution; but the precipitation is never complete by the dilution of conc. soln. The solubility of the hydroxide, and its sensitiveness to reagents, are much diminished if it has been dried by warming, or boiled for a long time in water. When beryllium hydroxide is first precipitated by alkalis it is

FIG. 2.—Solubilities of the Different Forms of Beryllium Hydroxide in Solutions of Potassium Hydroxide.

very voluminous, and absorbs carbon dioxide, and is easily soluble in potassium hydroxide and carbonate, in ammonium carbonate, and acids. On standing it gradually passes into a more stable form, which is granular, less affected by carbon dioxide, and is insoluble in potassium carbonate, dil. alkalies, and dil. acids. It is rapidly dissolved by hot 10N-KOH. When beryllium hydroxide is dissolved in glacial acetic acid about 90 per cent. can be extracted by shaking it with chloroform. Iron acetate is not extracted from its aq. soln. by chloroform; so that the separation of beryllium acetate is hence an easy one.

F. Haber and G. van Oordt² were so impressed by the change in the sensitiveness of beryllium hydroxide with ageing, that they postulated the existence of two modifications—the freshly precipitated form readily acted on by reagents, and the second older form produced by standing or by boiling the former; the aged form is much less readily attacked and is practically insoluble in acids and alkalies. G. van Oordt said that the *ageing of beryllium hydroxide* is produced by heating it in (i) a current of steam; (ii) in an aq. soln. of an indifferent compound like sodium carbonate or ammonia; or (iii) in a very dil. soln. of alkali hydroxide, potassium carbonate, etc.

C. L. Parsons and E. J. Roberts found that the freshly precipitated hydroxide, washed by cold water, will take up one-third of an eq. of **carbon dioxide**, while the boiled hydroxide or the hydroxide which has stood for a long time is but little affected by that gas. F. Sestini stated that beryllium hydroxide is almost insoluble in water charged with carbon dioxide—100 c.c. of water sat. with that gas at ordinary temp. dissolve 0.0185 gm. BeO. P. Raikow stated that a basic carbonate is probably formed. H. Rose found beryllium hydroxide to be readily soluble in **acids**; and to be decomposed by boiling with aq. soln. of **ammonium salts**; and under these conditions, J. J. Berzelius found that beryllium hydroxide dissolved, while aluminium hydroxide remained insoluble. W. Herz found beryllium hydroxide to be virtually insoluble in soln. of ammonium salts. H. J. Debray, C. A. Joy, and C. L. Parsons studied the same reaction. Basic beryllium acetate, $\text{Be}_4\text{O}(\text{C}_2\text{H}_3\text{O}_2)_6$, is a unique salt. The salt is prepared by dissolving the carbonate in hot glacial

acetic acid from which it separates. Beryllium also forms basic salts with formic, propionic, and butyric acids. The basic formate is difficult to purify by sublimation, (1) owing to the high temp. required, and (2) owing to its decomposition during sublimation; the basic acetate, $\text{Be}_4\text{O}(\text{C}_2\text{H}_3\text{O}_2)_6$, is readily sublimed without decomposition; it melts between 283° and 284° , and boils between 330° and 331° . It is almost insoluble in water, but is slowly hydrolyzed by cold and rapidly by hot water. It dissolves unchanged in many organic solvents—chloroform, alcohol, etc. The normal salt has not been made. Mineral acids liberate acetic acid. It is stable in dry air.

J. M. van Bemmelen found that after having been heated to redness, beryllium oxide is soluble only in boiling **sulphuric acid**. According to F. Toczyksky, beryllium hydroxide is nearly insoluble in **hydrocyanic acid**.

According to J. Weeren, freshly precipitated beryllium hydroxide is somewhat soluble in aq. **ammonia**, but not if ammonium chloride or sulphide is present; and, according to C. Renz, beryllium hydroxide is quite insoluble in **methylamine**, **ethylamine**, **dimethylamine**, and **diethylamine**. According to L. N. Vauquelin, a conc. soln. of **ammonium carbonate** slowly dissolves beryllium hydroxide; and conc. soln. of **sodium hydrocarbonate** act similarly. C. L. Parsons and S. K. Barnes found a boiling sat. soln. of sodium hydrocarbonate readily dissolves beryllium hydroxide, but it is almost insoluble in a dil. soln.; consequently, a conc. soln. of sodium hydrocarbonate which has dissolved beryllium hydroxide when diluted so as to contain 2 per cent. or less NaHCO_3 , slowly hydrolyzes in the cold, and deposits basic carbonate; the change occurs immediately if the soln. be boiled. Beryllium hydroxide is almost insoluble in a soln. of normal **sodium carbonate**, but, according to F. von Schaffgotsch, it dissolves in a soln. of **potassium carbonate**; and it is very slightly soluble, according to C. G. Gmelin, in a soln. of **lithium carbonate**.

According to C. G. Gmelin, beryllium hydroxide precipitated by aq. ammonia by the dilution of the soln. of beryllium hydroxide in aq. potassium carbonate, or after boiling with aq. ammonia, dissolves in a cold aq. soln. of **potassium or sodium hydroxide**; but that precipitated by boiling an alkaline soln. of beryllium hydroxide is not soluble in an aq. soln. of potassium hydroxide, ammonium carbonate, or potassium carbonate. J. Rubenbauer found the more conc. the soln. of sodium hydroxide the greater the proportion of beryllium hydroxide dissolved. Thus, at 20° , in grams per 100 c.c. of soln.:

NaOH	2.917	5.840	7.585	18.310
Be(OH) ₂	0.850	2.094	2.789	6.760

At room temp., the solubility of freshly precipitated beryllium hydroxide in 0.39*N*-, 0.65*N*-, and 1.99*N*-sodium hydroxide was respectively 0.06, 0.144, and 0.66 mols of beryllium hydroxide per litre. The solubilities of the hydroxide after drying for a week over sulphuric acid were about one-thirtieth of these values. F. Haber and G. van Oordt found for aq. soln. of sodium hydroxide in grams per litre of sat. soln.:

20°-23°				50°-53°				100°		
NaOH	.	.	.	0.5	1.0	2.0	0.5	1.0	2.0	0.5
BeO	.	.	.	0.060	0.170	0.570	0.080	0.230	0.900	0.080
										2.290
										1.020

J. K. Wood also measured the solubility of beryllium oxide in aq. soln. of sodium hydroxide. The hydrolysis of a boiling soln. of beryllium hydroxide in a lye of potassium or sodium hydroxide is not complete if an excess of base be present; indeed, the precipitation may be entirely or partially prevented by increasing the conc. of the alkali hydroxide.

H. Ley³ concluded that beryllium hydroxide is about eleven times as basic as aluminium hydroxide, and, like other colloidal hydroxides, it has a very great tendency to occlude other substances which may be present when it is precipitated; it is almost impossible to remove these substances by washing; as the adsorbed salts are washed out, the hydroxide passes through the filter paper. According to

J. M. van Bemmelen, the power of absorbing salts from aq. soln. is possessed by the colloidal β -hydroxide, not the crystalline α -hydroxide. M. Prud'homme, however, found that colloidal beryllium hydroxide does not act as a mordant and fix colouring matters like aluminium hydroxide.

The acidic qualities of the amphoteric beryllium oxide are illustrated by its forming a series of salts, **beryllonates** or **beryllates**, with the alkali hydroxides. Beryllium hydroxide thus behaves like a weak dibasic acid with the ions HBeO_2' and BeO_2'' . If the alkaline soln. be allowed to stand a long time, or if it be heated to boiling, almost all the beryllium hydroxide is precipitated. This subject is discussed in connection with the zincates. W. Ostwald added:

The question now arises why the chemical equilibrium, which has previously existed, is now disturbed, since no new substance has been added. The answer is to the effect that the beryllium hydroxide which is precipitated is a different, and indeed a more stable and less soluble form of the hydroxide than the freshly precipitated form which is soluble in alkalis. In other words, the newly prepared soln. is supersaturated with respect to the more stable form of the hydroxide, and therefore cannot continue to exist when the latter form is present. Since this form is not present in the newly prepared soln., the precipitation can commence only after the first traces of it have been formed. At the ordinary temp. this occurs slowly but quickly when heated.

The action of the alkali hydroxides on beryllium oxide and hydroxide has already been discussed. G. Krüss and H. Moraht prepared **potassium beryllate**, K_2BeO_2 , or $\text{Be}(\text{OK})_2$, by saturating a soln. of potassium hydroxide in absolute alcohol with freshly precipitated beryllium hydroxide; filtering through asbestos in a silver funnel; and evaporating the soln. over sulphuric acid. A crop of crystals of potassium carbonate mixed with beryllium hydroxide first separates; the soln. is then filtered; and, on further evaporation, a white mass is obtained, which is washed with alcohol. A similar result is obtained by working with aq. soln., but the product is more impure. The salt is very hygroscopic, readily soluble in water, sparingly soluble in cold dil. hydrochloric acid; and very easily attacked by the carbon dioxide of the atm. Analyses always furnish rather too high a value for potassium than is needed for $\text{Be}(\text{OK})_2$. G. Krüss and H. Moraht obtained **sodium beryllate**, $\text{Be}(\text{ONa})_2$, in a similar manner, and it possessed properties similar to those of the potassium salt. J. K. Wood found that about 40 per cent. of an aq. soln. of sodium beryllate is hydrolyzed in $\frac{1}{10}$ N-soln. at 25° . A. Hantzsch measured the electrical conductivity of soln. of the alkali beryllates, zincates, plumbates, stannates, and germanates; and also the rate at which the soln. saponify ethyl acetate. He hence inferred that the hydroxides of zinc, beryllium, lead, tin, and germanium all act as acids, in this order of increasing strength; zinc and beryllium hydroxides are very weak acids, and the zinc hydroxide in alkaline soln. appears to exist mostly in the colloidal form. All five hydroxides act as monobasic acids under the conditions just indicated. The order of the hydroxides just indicated is not exactly the reverse of their order if arranged according to their strength as bases.

A. S. Komarovskiy⁴ attempted to make **beryllium dioxide** by the action of hydrogen peroxide on hydrated beryllium oxide, but obtained a compound with hydrogen peroxide of crystallization — **beryllium hydroperoxyhydroxide**, $3\text{BeO} \cdot 4\text{H}_2\text{O}_2 \cdot 8\text{H}_2\text{O}$. Basic beryllium carbonate, $\text{BeCO}_3 \cdot 5\text{BeO} \cdot 8\text{H}_2\text{O}$, by a similar treatment yields a basic dioxide, **beryllium oxydioxide**, $2\text{BeO}_2 \cdot 3\text{BeO} \cdot 8\frac{1}{2}\text{H}_2\text{O}$, which is moderately stable and exhibits the general characteristics of peroxides.

§ 7. Beryllium or Glucinum Fluoride

In 1811, J. L. Gay Lussac and L. J. Thénard¹ precipitated a fluoride of beryllium by adding acid potassium fluoride to a soln. of beryllium oxide in hydrochloric acid; and in 1823 J. J. Berzelius also made a beryllium fluoride by dissolving the oxide in hydrofluoric acid, and he described the properties of the soln., and recognized that the gum-like residue obtained on evaporation has basic properties. G. Klatzo also made some observations on the fluoride in 1869. A. Cossa and D. Pecile made beryllium fluoride by heating magnesium fluoride with beryllium sulphate. The pure salt, BeF_2 , however, does not appear to have been produced until P. Lebeau's *Recherches sur le glucinum et ses composés* (1898). P. Lebeau showed that all water must be absent, for the hydrolysis which occurs during the evaporation of the aq. soln. leads to the escape of hydrogen fluoride, and the soln. becomes more and more basic, for it can hold comparatively large amounts of the hydroxide in soln. By evaporating the soln. in the presence of ammonium fluoride, or in an atm. of hydrogen fluoride, the hydrolysis can be very considerably reduced. P. Lebeau made beryllium fluoride of a high degree of purity by heating the thoroughly dried double fluoride of beryllium and ammonium, $\text{BeF}_2 \cdot 2\text{NH}_4\text{F}$, in a stream of dry carbon dioxide, and cooling the product in an atm. of the same gas. He also made the fluoride by the action of gaseous hydrogen fluoride on beryllium carbide.

P. Lebeau has also described the properties of the salt he prepared. Anhydrous beryllium fluoride is a transparent glass-like mass with a sp. gr. 2.01 (15°). When heated it becomes viscous, and then more and more fluid as the temp. rises; it is a mobile liquid at 800°; and at this temp. it begins to volatilize, forming a sublimate of white deliquescent crystals. According to E. Peterson the heat of the reaction $\text{Be}(\text{OH})_2 + 2\text{F}_{\text{aq}} = 19.683 \text{ Cals.}$; and O. Mulert, 20.47 Cals. For the heat of formation from beryllium hydroxide and hydrofluoric acid, *vide supra*. S. Datta studied the spectrum of beryllium fluoride. The salt does not conduct electricity. The salt dissolves in all proportions in water. Owing to the hydrolysis of aq. soln. almost any degree of basicity can be obtained, and an indefinitely large number of **beryllium oxyfluorides** produced if analysis be the only evidence of chemical individuality. P. Lebeau says the product obtained by heating the residue obtained by the evaporation of a soln. of beryllium oxide in hydrofluoric acid, and ignition at 800° is a porcelain-like substance which always has a constant composition, $2\text{BeO} \cdot 5\text{BeF}_2$, and a sp. gr. 2.3. The product forms a clear soln. with water. Beryllium fluoride is only slightly soluble in absolute alcohol, but dissolves readily in 90 per cent. alcohol.

On cooling the alcoholic soln. to -23° , a white crystalline mass is obtained which melts as the temp. rises. The salt is also slightly soluble in a mixture of alcohol and ether.

The majority of the metalloids have no action on beryllium fluoride; when heated with oxygen the fluoride is partly decomposed into an oxyfluoride or more probably oxide. Sulphur vapour has no action at 75° ; it is virtually insoluble in anhydrous hydrofluoric acid, and does not form a compound; with conc. sulphuric acid, it forms hydrofluoric acid and beryllium sulphate. The alkali metals and magnesium at a red heat reduce the fluoride to metallic beryllium, but the hygroscopicity and the difficulty of fusion render the process unsuited for the preparation of the metal; the action with potassium begins at 450° ; with lithium and magnesium at about 650° ; and aluminium may be fused with beryllium fluoride without alteration.

In 1811, J. L. Gay Lussac and L. J. Thénard, and J. J. Berzelius in 1823, prepared **potassium beryllium fluoride**, $\text{BeF}_2 \cdot 2\text{KF}$, but they made no analyses. This salt was further studied by A. von Awdejef. Rhombic bipyramidal crystals of the salt are formed by evaporating a mixture of the constituent salts. J. C. G. de Marignac gives the axial ratios $a:b:c=0.5708:1:0.7395$. The crystals are soluble in 50 parts of water at 20° , and in 19 parts of boiling water. The salt decrepitates when heated and fuses at a red heat. According to H. Debray, if a large excess of beryllium fluoride be present, a solid $\text{BeF}_2 \cdot \text{KF}$ is formed, but when recrystallized, crystals of $\text{BeF}_2 \cdot 2\text{KF}$ are produced. These salts were also studied by W. Gibbs, and by J. C. G. de Marignac. The individuality of $\text{KF} \cdot \text{BeF}_2$ may be questioned, but G. Klatzo doubts the existence of both salts; P. Lebeau and J. C. G. de Marignac believe both salts exist. Similar remarks apply to two **sodium beryllium fluorides**, $\text{BeF}_2 \cdot \text{NaF}$ and $\text{BeF}_2 \cdot 2\text{NaF}$, prepared by J. C. G. de Marignac; and again, it is the last-named form which is the more readily obtained in crystals. Both salts crystallize in rhombohedral prisms. According to J. C. G. de Marignac, the salt $\text{BeF}_2 \cdot 2\text{NaF}$ is dimorphous, furnishing both rhombic crystals with axial ratios $a:b:c=0.8243:1:0.3693$; and monoclinic crystals with axial ratios $a:b:c=0.6929:1:0.9913$, and $\beta=99^{\circ} 20'$. J. C. G. de Marignac failed to get definite crystals of $\text{NaF} \cdot \text{BeF}_2$, and, as in the case of the corresponding potassium compound, its individuality is open to doubt. J. C. G. de Marignac prepared crystals of **ammonium beryllium fluoride**, $\text{BeF}_2 \cdot 2\text{NH}_4\text{F}$, by evaporating a soln. of the component salts; and H. von Helmsolt by evaporating a soln. of beryllium hydroxide and ammonium fluoride. The crystals are either colourless needles or prisms belonging to the rhombic system with axial ratios, according to J. C. G. de Marignac, $a:b:c=0.5688:1:0.7367$, and isomorphous with $\text{BeF}_2 \cdot 2\text{KF}$. When heated the salt decrepitates, melts, and then decomposes with the evolution of ammonium fluoride. According to H. von Helmsolt, the beryllium is not completely precipitated by ammonia from the aq. soln. of this salt.

§ 8. Beryllium or Glucinum Chloride

L. N. Vauquelin¹ obtained a soln. of the chloride in 1798, but if the attempt be made to isolate the chloride by evaporating the aq. soln., hydrolysis attended by the loss of hydrogen chloride leaves a basic salt as residue. Much of the hydrolysis, but not all, can be prevented by evaporation in the presence of ammonium chloride, or in a stream of hydrogen chloride. The anhydrous chloride, however, cannot be prepared from the hydrated salt obtained from aq. soln. by heating it in dry hydrogen chloride or in dry chlorine; the water is retained too tenaciously by the salt. Anhydrous beryllium chloride, BeCl_2 , was not prepared until H. Rose obtained the sublimed salt in 1828 by the action of a stream of chlorine gas on an intimate mixture of carbon and beryllium oxide. Whatever be the method of preparation, the materials must be thoroughly dried if the anhydrous chloride is to have a high degree of purity. F. Wöhler prepared the salt by H. Rose's process, and also by warming the metal in chlorine gas. The metal burns brilliantly, and the chloride is sublimed. Similar methods were used by A. von Awdejef, A. A. B. Bussy, H. J. Debray, G. Klatzo, L. F. Nilson and O. Pettersson, J. H. Pollok and T. S. Humpidge. L. F. Nilson and O. Pettersson also prepared the anhydrous chloride by the action of dry hydrogen chloride on the metal. H. J. Debray passed hydrogen chloride over the heated oxide, and P. Lebeau made the chloride by the action of chlorine or hydrogen chloride on heated beryllium carbide. L. Meyer passed carbon tetrachloride over heated beryllium oxide; F. Bourion, a mixture of chlorine and sulphur chloride, S_2Cl_2 . H. Rose (1848) also calcined the oxide, carbonate, or sulphate with ammonium chloride. According to K. Mieleitner and H. Steinmetz, when an ice-cold aq. soln. of beryllium chloride in ether or alcohol is sat. with hydrogen chloride, and the product is dried in vacuo, crystals of *tetrahydrated beryllium chloride*, $\text{BeCl}_2 \cdot 4\text{H}_2\text{O}$, are formed; the crystals were said to contain no combined ether or alcohol. Every attempt by C. L. Parsons to make the tetrahydrated beryllium chloride, $\text{BeCl}_2 \cdot 4\text{H}_2\text{O}$, prepared by A. von Awdejef, met with failure, no crystalline chloride of any degree of hydration could be obtained, and he doubts the existence of such a compound.

Beryllium chloride is a white crystalline solid which, according to P. Lebeau, has the **melting point** 440° ; T. Carnelley's 601° is much too high—J. H. Pollok's value is "about 400° ." L. F. Nilson and O. Pettersson give the **boiling point** 520° , a number confirmed by J. H. Pollok. L. F. Nilson and O. Pettersson's value for the vapour density between 490° and 1520° is in agreement with the formula BeCl_2 , and this was confirmed by T. S. Humpidge. The **molecular weight** determined by A. Rosenheim and P. Woge from the b.p. of soln. of beryllium chloride in pyridine is also in agreement with BeCl_2 . J. H. Pollok's value for the **heat of formation** is (Be, Cl_2) 155 Cals.; W. Mielenz and H. von Wartenberg gave $(\text{Be}, \text{Cl}_2) = 112.6 \pm 0.4$ Cals. for the heat of formation from beryllium hydroxide and hydrochloric acid, *vide supra*; the **heat of solution** of beryllium in hydrochloric acid is 199.5 Cals.; the mol. ht. of soln. in water 44.5 Cals.; and in alcohol 37.4 Cals. S. Meyer's value for the **magnetic susceptibility** is -0.463×10^{-6} units per gram, or -0.038×10^{-6} per mol. P. Lebeau says that the molten chloride does not conduct the electric current; W. Hampe says it does.

Beryllium chloride very readily hydrolyzes in presence of moisture—even that absorbed from the atm. The residue has this peculiarity; it readily dissolves in water in accord with the fact that one eq. of hydrochloric acid will dissolve several eq. of the carbonate. The chloride which has absorbed a trace of moisture loses chlorine, for it gives too low a value for the ratio $\text{Be} : \text{Cl}$, and this even when the air is dried with calcium chloride. Hence the very great care required to exclude moisture from the chloride in such determinations. Similar remarks apply to the acetate, sulphate, etc. Magnesium chloride also requires great care in drying to avoid loss of chloride resulting from the absorption of moisture from the air. When an aq. soln. of beryllium chloride is evaporated, hydrogen chloride is evolved.

J. H. Pollok found the alcoholic soln. is a conductor of electricity. According to R. Höber and F. Kiesow, the taste of soln. of beryllium chloride is due to the cation.

Beryllium chloride dissolves with great avidity in **water**, and the process is attended by a hissing sound. The soln. is hydrolyzed: $\text{BeCl}_2 + 2\text{H}_2\text{O} \rightleftharpoons \text{Be}(\text{OH})_2 + 2\text{HCl}$, but less than the corresponding soln. of ferric or aluminium chloride. The aq. soln. have an acid reaction. The solubility of the salt and the degree of hydrolysis are both reduced by the addition of free acid. H. Ley's and L. Bruner's values for the hydrolysis of aq. soln. with 12 and 20 gram-eq. per litre are respectively 2.1 and 2.2 per cent.; and at 99.7°, with an increase from 64 to 512 gram-eq. per litre, the hydrolysis increases from 5.18 to 11.2 per cent. J. K. Wood found the **hydrolysis constant** of a *N*-soln. of beryllium chloride at 25° is 0.000232, and about 1.5 per cent. of the salt is hydrolyzed; he represents the first stage of the hydrolysis by $\text{BeCl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{Be}(\text{OH})\text{Cl} + \text{HCl}$. A. Heydweiller measured the sp. gr., *D*, and the **electrical conductivity**, λ , of soln. with *m* eq. of the salt per litre; δD represents the values of $(D-1) \times 10^4$ reduced to a vacuum:

<i>m</i>	.	.	.	0.5	1.0	2.0	3.0	4.0
δD	.	.	.	130.9	259.5	511	761	1008
λ	.	.	.	58.4	51.6	42.03	34.42	29

and the residue which remains may have almost any degree of basicity according to the conditions which obtain. The evaporation of the soln. in a stream of hydrogen chloride, or mixed with ammonium chloride, and subsequent volatilization of the ammonium chloride, does not prevent the hydrolysis of the chloride. Hence, many announcements have been made of the preparation of **beryllium oxychlorides**, but these are based merely on analysis—*e.g.* A. Atterberg's claim to have made a gum-like mass of the oxychloride by the evaporation of the hydrochloric acid soln. of beryllium hydroxide; or of a soln. of beryllium chloride with the carbonate; or by precipitating a cold soln. of the chloride with ammonia. Similarly, A. von Awdejef, A. Atterberg, and G. Krüss and H. Moraht thought they had produced **tetrahydrated beryllium oxychloride**, $\text{BeO} \cdot \text{BeCl}_2 \cdot 4\text{H}_2\text{O}$, by the slow evaporation of the chloride over sulphuric acid, but C. L. Parsons has shown that this process gives basic mixtures of varying degrees of hydration, and the product is probably a mixture of beryllium chloride and beryllium hydroxide in varying proportions. J. H. Pollok's claim to have separated beryllium chloride by fractional sublimation into a mixture of two products with different eq. was shown by C. L. Parsons to be explained by the action of water on beryllium chloride, "and that insufficient precautions were taken to guard against the presence of moisture."

According to A. Atterberg, beryllium chloride is soluble in **ether** with which it forms a crystalline compound, $\text{BeCl}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$; according to P. Lebeau, it behaves similarly with **alcohol**, and is but sparingly soluble in **benzene**, **chloroform**, **carbon tetrachloride**, and **carbon disulphide**. P. Lebeau also obtained compounds of beryllium chloride with **ammonia**, **phosphine**, and many organic bases—*e.g.* pyridine—but C. Renz was able to obtain only the quinoline compounds. According to K. Mieleitner and H. Steinmetz, the cold sublimed chloride readily unites with dry ammonia, forming **beryllium tetrammino-chloride**, $\text{Be}(\text{NH}_3)_4\text{Cl}_2$; whereas if the mixture becomes hot, **beryllium diammino-chloride**, $\text{Be}(\text{NH}_3)_2\text{Cl}_2$, is formed. F. Ephraim prepared **beryllium hexammino-chloride**, $[\text{Be}(\text{NH}_3)_6]\text{Cl}_2$, which decomposed before the dissociation press. of 500° was reached. C. L. Parsons also crystallized a compound of beryllium chloride, ether, water, and hydrogen chloride from an aq. soln. of beryllium chloride sat. with hydrogen chloride mixed with an equal vol. of ether sat. with the same gas, but K. Mieleitner and H. Steinmetz showed that the product contains no combined ether. The marked hydrolysis, the combination with, and the solubility in, organic solvents are outstanding characteristics of beryllium chloride. A. von Awdejef, L. F. Nilson and O. Pettersson, and T. S. Humpidge state that beryllium chloride attacks **glass**; but, according to C. L. Parsons, beryllium chloride can be sublimed in hard potash glass, without the

slightest sign of action, provided all moisture is absent. The least moisture causes a thin film of oxide to form and adhere tenaciously to the glass. This film can easily be mistaken for corrosion. According to P. Lebeau, beryllium chloride does not give Friedel and Craft's reaction. Sulphur vapour heated with beryllium chloride forms beryllium sulphide, and sulphur chloride; hydrogen sulphide also converts red-hot beryllium chloride into the sulphide.

While normal beryllium chloride cannot be readily produced in the presence of water, the double-salts are much more stable, and are very much less subject to the confusing effects of hydrolysis. A. Welkow² failed to prepare double compounds of beryllium chloride with the chlorides of potassium or sodium; and H. L. Wells and G. F. Campbell failed to prepare the double chloride of beryllium and caesium; in every case the single salts crystallized side by side from the mixed soln., and there were no indications of the formation of a double salt even at low temp. Beryllium thus falls in line with the series Be, Mg, Zn, Cd, Hg, in which the tendency to form double halogen salts increases with the at. wt. A. Atterberg obtained double pyramidal crystals of auric beryllium chloride, $\text{AuCl}_3 \cdot \text{BeCl}_2$, from a soln. of eq. quantities of the component salts; and the later crop of crystals were $\text{BeCl}_2 \cdot 2\text{AuCl}_3$. R. F. Weinland and F. Schlegelmilch prepared unstable hygroscopic golden-yellow needles of beryllium iodic chloride, $2\text{ICl}_3 \cdot \text{BeCl}_2 \cdot 8\text{H}_2\text{O}$, by passing chlorine into a hydrochloric acid soln. of beryllium chloride and iodine at 10° .

§ 9. Beryllium or Glucinum Bromide

A. J. Balard¹ suspended beryllium hydroxide in bromine-water and found that very little passed into soln. as bromide or bromate; nor did the liquid possess bleaching qualities. F. Wöhler made the bromide by burning the metal in bromine vapour and also by the action of bromine on a heated mixture of beryllium oxide and carbon. T. S. Humpidge used a similar process, and P. Lebeau passed bromine or hydrogen bromide over heated beryllium carbide. J. B. Berthemot made a soln. of the bromide by dissolving the oxide in hydrobromic acid, and says that on evaporation crystals of beryllium bromide are formed, but A. Atterberg could not confirm this.

Anhydrous beryllium bromide sublimes in long colourless crystals, and the vapour density, according to T. S. Humpidge, is in accord with the formula BeBr_2 . T. Carnelley and W. C. Williams gave the m.p. 600° , a number which, according to P. Lebeau, is far too high; P. Lebeau's value is 490° , and he states that volatilization occurs below this temp. According to P. Lebeau, the fused salt does not conduct electricity; but W. Hampe says it does, and H. N. Warren obtained the metal by the electrolysis of the fused bromide. The bromide dissolves in water with avidity, and much heat is developed. As in the case of beryllium chloride, the soln. of the bromide is much hydrolyzed: $\text{BeBr}_2 + 2\text{H}_2\text{O} \rightleftharpoons \text{Be}(\text{OH})_2 + 2\text{HBr}$. According to J. M. Ordway, beryllium forms a basic bromide, but the remarks with reference to the oxychlorides apply also to the **beryllium oxybromides**. Beryllium bromide dissolves readily in alcohol, with which it forms a crystalline compound; and it also combines with ammonia and organic bases.

§ 10. Beryllium or Glucinum Iodide

F. Wöhler ¹ prepared a sublimate of beryllium iodide, BeI_2 , in 1828, by burning the metal in the vapour of iodine; H. J. Debray, also, in 1875, prepared this salt by passing the vapour of iodine over the red-hot metal. We have to depend upon the work of P. Lebeau, *Sur l'iodure de glucinum*, for our knowledge of the properties of this salt; he prepared it by leading dry hydrogen iodide or iodine vapour over beryllium carbide, Be_2C , confined in a porcelain boat, in a combustion tube at 700° ; the salt sublimes and collects in the cooler parts of the tube. It can be preserved in an atm. of dry carbon dioxide. According to P. Lebeau, sublimed beryllium iodide forms colourless needle-like crystals, which are quickly decomposed in moist air. The sp. gr. of the salt at 15° is nearly 4.2. The crystals melt at 510° , and begin to sublime below this temp.; according to H. J. Debray, the iodide is less volatile than the chloride. The iodide boils between 585° and 595° . The slightest trace of water attacks beryllium iodide immediately, but it is not so sensitive after fusion, probably because less surface is exposed. J. M. Ordway claims to have made **beryllium oxyiodide**, but there is no satisfactory evidence of the individuality of such a compound. Beryllium iodide is insoluble in benzene, toluene, and turpentine, and very sparingly soluble in carbon disulphide. Beryllium iodide is soluble in alcohol with which it forms a crystalline compound; likewise also with ether. Unlike aluminium iodide, it does not react upon cold carbon tetrachloride; nor does it react with carbon hexachloride, C_2Cl_6 . It reacts energetically with acetic anhydride, anhydrous chloral, and a large number of organic compounds. Ammonium compounds and organic bases—e.g. aniline and pyridine—form crystalline compounds with beryllium iodide.

When beryllium iodide is heated in oxygen it takes fire near a red heat, forming, according to H. J. Debray, beryllium oxide and iodine. Beryllium iodide vapour burns in air, it can be distilled unchanged in dry hydrogen, nitrogen, or carbon dioxide; but chlorine or bromine readily displace the iodine, and fluorine both displaces the iodine and unites with it, forming iodine fluoride—the attack by chlorine

and fluorine proceeds in the cold with the evolution of light and heat. Sulphur acts on heated beryllium iodide, forming beryllium sulphide; hydrogen sulphide forms white sulphide; and phosphorus, beryllium phosphide; at a red heat, cyanogen reacts with beryllium iodide, forming a white solid, which is less volatile than the iodide, and which with water gives a soln. reacting like a cyanide and is probably *beryllium cyanide*, BeCy_2 . Beryllium iodide in the cold absorbs large amounts of ammonia, forming white pulverulent **beryllium sesquiammino-iodide**, $2\text{BeI}_2 \cdot 3\text{NH}_3$, which melts readily and crystallizes on cooling. If heated in ammonia gas, a higher ammino-compound appears to be formed. Sodium, potassium, and lithium reduce beryllium iodide at about 350° ; magnesium, at about 450° ; and aluminium, silver, copper, and mercury do not react below the temp. of the softening of glass.

§ 11. Beryllium or Glucinum Sulphide and Sulphates

L. N. Vauquelin¹ found that beryllium oxide is not changed when heated with sulphur. F. Wöhler believed that he had made **beryllium sulphide** by heating the metal with molten sulphur, but both H. Debray, and L. F. Nilson and O. Pettersson failed to get evidence of a combination of the two elements, nor could E. Frémy produce the sulphide by passing the vapour of carbon disulphide over heated beryllium oxide. J. J. Berzelius claimed to have made a double sulphide of beryllium and tungsten, but this has not been confirmed. P. Lebeau, however, made beryllium sulphide by heating the anhydrous chloride or iodide with sulphur or with hydrogen sulphide; and by the action of sulphur vapour on the carbide at a high temp. K. Mieleitner and H. Steinmetz prepared it by heating beryllium chloride in hydrogen sulphide purified by means of a chromous salt and phosphoric acid. Beryllium sulphide is a white pulverulent solid, which P. Lebeau said is immediately decomposed by water, but which, according to K. Mieleitner and H. Steinmetz, is little decomposed by water even when boiling; but is readily attacked by acids including atm. carbon dioxide. It burns with a bright flame; in contact with conc. nitric acid, sulphur is separated; dry hydrogen chloride, at a red heat, converts it into the chloride; and dry bromine, at a red heat, converts it into the bromide. A *beryllium polysulphide* has not been prepared.

In 1798, L. N. Vauquelin² prepared a gummy mass of basic sulphate by the action of sulphuric acid on beryllia. J. J. Berzelius, and H. R. Gmelin studied the beryllium sulphates in 1815, and prepared a compound which was regarded as a hydro- or acid sulphate, but which A. von Awdejef proved to be **tetrahydrated beryllium sulphate**, $\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$, and he employed this salt to determine the at. wt. of beryllium. Several others—J. Weeren, G. Klatzo, L. F. Nilson and O. Pettersson, and G. Krüss and H. Moraht—employed the salt for the same purpose, but C. L. Parsons showed that when confined over phosphoric oxide, the salt lost water continuously and is not suited for determining the at. wt. of the element. Anhydrous **beryllium sulphate**, BeSO_4 , and five hydrates— $\text{BeSO}_4 \cdot \text{H}_2\text{O}$, $2\text{H}_2\text{O}$, $4\text{H}_2\text{O}$, $6\text{H}_2\text{O}$, and $7\text{H}_2\text{O}$ —have been reported, but the evidence for the heptahydrate is probably not well founded. L. F. Nilson and O. Pettersson prepared a product, which they regarded as the anhydrous sulphate, by heating the hydrate to 250° ; and M. Levi-Malvano obtained it by gradually heating the hydrate to 180° , and he claims to have completely eliminated all the water between 218° and 220° . According to C. L. Parsons, however, the water of crystallization is not all expelled even at 250° ; and there is no sharply defined line between the points where all the water is driven

off, and where sulphuric anhydride begins to be evolved, in fact, they come off together over a considerable range of temp. A product which is almost anhydrous and which has lost no sulphuric anhydride can be obtained at a temp. near the b.p. of sulphur. P. Lebeau prepared an anhydrous sulphate by the action of conc. sulphuric acid on beryllium oxide, and evaporating off the excess of acid. Here again C. L. Parsons claims that it is next to impossible to evaporate the last traces of free acid and water resulting from its decomposition, without decomposing a small amount of the sulphate, and furnishing a product which leaves a small proportion of residue after the main portion has dissolved.

Tetrahydrated beryllium sulphate was prepared by J. J. Berzelius by dissolving the oxide, hydroxide, or carbonate in an excess of sulphuric acid, and removing the excess of acid by evaporation. The crystals were washed with alcohol. A. von Awdejff recrystallized Berzelius' product from hot water.

C. L. Parsons proceeds by evaporating the sulphuric acid soln. of beryllia in a platinum dish, and heating it below a red heat until the larger part but not all the white fumes of sulphuric acid have been driven off. The product is dissolved in water, evaporated to the point of crystallization. A very slight excess of beryllia in the soln. prevents the formation of the crystals, and yields a non-crystallizable syrup. The crystals can then be purified by washing with conc. alcohol, re-solution in water, evaporation to a syrup and pouring, while hot, into excess of conc. alcohol. The soln. is at first colloidal, but after some hours the $\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$ crystallizes out almost completely. By repetition, the last traces of sulphuric acid may be removed; or, more quickly, beryllium oxide may be dissolved in conc. sulphuric acid in a platinum dish and the excess of sulphuric acid be driven off by a Bunsen burner, held in the hand. Care must be used to heat but little higher than necessary to remove the excess of acid. The mixture of anhydrous sulphate with a little oxide, resulting from its own decomposition, is then treated with water and allowed to stand. While quite insoluble at first, the sulphate will have dissolved in the course of one or two days. Filtration from the undissolved oxide and crystallization yields a product of a fair degree of purity.

A. Atterberg prepared **dihydrated beryllium sulphate**, $\text{BeSO}_4 \cdot 2\text{H}_2\text{O}$, by drying the tetrahydrate at 100° . It was also prepared by L. F. Nilson and O. Pettersson, and G. Krüss and H. Moraht. C. L. Parsons showed that the dihydrate is fairly stable in dry air at ordinary temp., but between 100° and 110° , it slowly loses water, and, with sufficient time, the loss is continuous. The transition temp. for the tetrahydrate and the dihydrate is 113.6° , as illustrated in Fig. 3. If alcohol be added to the soln. at a temp. below 100° , or if the soln. be evaporated below this temp., the tetrahydrate is formed, and if above 100° , the dihydrate appears. M. Levi-Malvano claimed that in a sealed tube at 158° , the dihydrate passes into **monohydrated beryllium sulphate**, $\text{BeSO}_4 \cdot \text{H}_2\text{O}$. Progressive dehydration, by heating, of the tetrahydrate of beryllium sulphate confirms the existence of the di- and monohydrates, the former being obtained at 55° – 60° and the latter at 100° , indicating the existence of a hemihydrate obtainable at 150° – 160° . The anhydrous salt obtained at 250° is stable up to 530° – 540° , and thus allows of the estimation of beryllium in the form of its sulphate.

G. Klatzo claimed to have prepared monoclinic prisms of **heptahydrated beryllium sulphate**, $\text{BeSO}_4 \cdot 7\text{H}_2\text{O}$, from a strongly acid soln., but C. L. Parsons showed that the conditions which G. Klatzo described for the preparation of the heptahydrate do not furnish any such salt. The analogies between beryllium and magnesium salts probably misled G. Klatzo into believing that possibly an imperfectly dried sulphate was analogous in composition with heptahydrated magnesium sulphate. J. C. G. de Marignac once obtained a mass of efflorescent prismatic crystals, of what he regarded as **hexahydrated beryllium sulphate**, $\text{BeSO}_4 \cdot 6\text{H}_2\text{O}$, by evaporating a supersaturated soln. of sodium and beryllium sulphates. M. Levi-Malvano could not obtain crystals of the hexahydrate from soln. of the tetrahydrate; but he obtained them by the action of an excess of slightly diluted sulphuric acid on enough beryllium hydroxide or carbonate, at ordinary temp., to ensure a state of supersaturation of the sulphate. By suddenly shaking the mass, crystallization occurred. The soln. should contain an excess of acid, and inoculation with crystals of the hexahydrate

does not appear of any assistance. Crystallization in the cold did not specially favour the formation of the hexahydrate; but supersaturation seemed to be the one necessary condition. C. L. Parsons and C. T. Fuller made many attempts to produce the hexahydrate, but without success, and they attributed their failure to the omission of some essential condition other than supersaturation. Once the hexahydrate had been produced, M. Levi-Malvano found that it crystallized from aq. soln. at temp. as high as 50° , and he even threw it out of soln. at 90° by the addition of boiling alcohol; at -30° , the cryohydrate, a mixture of ice and the hexahydrate, was formed. F. Wirth also said that the solid phase in contact with sulphuric acid up to 13*N*-soln. is the hexahydrate, but H. T. S. Britton could obtain no evidence of the existence of the hexahydrate; he repeated F. Wirth's observations, and generally concluded that "if the hexahydrate does exist, the conditions for its preparation have not yet been described."

According to C. L. Parsons, anhydrous beryllium sulphate is almost insoluble in water, but it is slowly converted by cold water, and rapidly by hot water, into the tetrahydrate. The solubility of beryllium sulphate has been determined by M. Levi-Malvano. He found for the stable system:

	30.0°	40.0°	68.0°	85.0°	95.4°	107.2°	111.0°	113.6°	119.0°
Per cent. BeSO_4	30.5	31.9	38.3	43.3	47.5	53.6	56.2	—	59.9
Solid phases				$\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$				$\text{BeSO}_4 \cdot 2\text{H}_2\text{O}$	

where 113.6° is the transition temp. from the tetrahydrate to the dihydrate. For the metastable system, he found:

	31.0°	50.0°	72.2°	77.4°	80.0°	91.4°	105.0°
Per cent. BeSO_4	34.4	37.8	42.9	45.0	45.9	49.5	54.2
Solid phases			$\text{BeSO}_4 \cdot 6\text{H}_2\text{O}$		$\text{BeSO}_4 \cdot 2\text{H}_2\text{O}$		

The results are plotted in Fig. 3. There is a transition temp. at 77.4° for the metastable hexahydrate and the metastable dihydrate. As indicated above, the dihydrate passes into the monohydrate at 158° . Beryllium sulphate thus appears to be soluble in its own weight of water, but, as F. Ephraim has emphasized, the numbers are affected by an error due to the fact that the tetrahydrate was obtained from soln. with an excess of sulphuric acid, and F. Wirth obtained lower values for the solubilities. For example, M. Levi-Malvano obtained a solubility of one mol of BeSO_4 per 11.18 mols of water at 31° and one mol of BeSO_4 per 11.5 mol of water at 25° ; or, 100 grms. of soln. contain 33.67 grms. of BeSO_4 , or 100 grms. of water dissolve 50.78 grms. of BeSO_4 . F. Wirth found 8.262 grms., or 0.07857 mols of BeSO_4 , in 100 grms. of soln. The addition of small proportions of sulphuric acid lowers the solubility of beryllium sulphate but slightly; and with proportions beyond 12.5*N*-acid, the hexahydrate passes into the tetrahydrate, and the solubility decreases much further. The solubility in 20*N*-acid is about one-fourth of the value for water. F. Wirth gives for sulphuric acid of different normality, the following solubilities at 25° in grams per 100 grms. of soln.:

H_2SO_4	0	1.1	2.11	4.32	10.8	12.6	14.5	16.96	20.78	24.92
BeSO_4	8.212	8.429	7.944	6.603	5.773	6.628	5.438	3.640	2.128	2.185

Fig. 3.—Solubility Curves of Beryllium Sulphate.

The results are plotted in Fig. 4. H. T. S. Britton's results at 25° are quite different. He found the solid phase in all cases to be the tetrahydrate, and expressing the normality of the sulphuric acid by *N*, and the conc. of the soln. in grms. BeSO_4 per 100 grms. of sat. soln., he found:

<i>N</i>	.	.	0	3.39	5.01	8.66	13.23	16.70	19.23	20.70
BeSO_4	.	.	29.94	20.51	15.91	8.61	3.54	2.04	0.98	0.86

According to F. Taboury, dihydrated beryllium sulphate crystallizes from a conc. soln. of sulphuric acid, and the tetrahydrate crystallizes from a dil. soln. Magnesium sulphate crystallizes from a soln. containing much magnesium chloride and then retains four in place of seven mols of water. There is no evidence of the formation of an acid or hydro-sulphate. Tetrahydrated beryllium sulphate is insoluble in absolute alcohol; but, according to J. Thomsen, and H. Debray, aq. alcohol dissolves marked quantities of the salt.

FIG. 4.—Solubility of Beryllium Sulphate in Sulphuric Acid at 25°.

According to A. von Awdejef, the bipyramidal crystals of tetrahydrated beryllium sulphate belong to the tetragonal system, and, according to H. Töpsöe, the axial ratios are $a:c = 1:0.9461$. Observations have been made by A. E. Nordenskjöld, and G. Wulff on the multiple twinning of the crystals. According to G. Klatzo, the crystals of the unconfirmed heptahydrate are monoclinic prisms.

Mixed crystals of beryllium and aluminium sulphates were studied by G. Brügelmann; J. C. G. de Marignac, A. Atterberg, and J. W. Retgers observed no signs of the formation of mixed crystals with the sulphates of copper, magnesium, zinc, manganese, iron, or nickel. According to F. Zambonini, the hexahydrate furnishes cubic crystals. L. F. Nilson and O. Pettersson gave 2.443 for the **specific gravity** of anhydrous beryllium sulphate. For tetrahydrated beryllium sulphate, H. Töpsöe gave 1.725; L. F. Nilson and O. Pettersson, 1.713; G. Krüss and H. Moraht, 1.7125 at 10.5°; and H. Stallo, 1.6743 at 22°. H. Jahn, and H. Traube measured the **molecular solution volume** of beryllium sulphate soln. with 11.283 and 20.281 per cent. soln. of beryllium sulphate and found the respective sp. gr. to be 1.09366 and 1.17874, and the mol. soln. vol. to be 23.9 and 25.7 at 14°. Beryllium has a greater soln. vol. than is usually the case with bivalent elements. J. Wagner found the **viscosity** of *N*-, $\frac{1}{2}$ *N*-, $\frac{1}{4}$ *N*-, and $\frac{1}{16}$ *N*-soln. of beryllium sulphate, at 25°, to be respectively 1.3600, 1.1620, 1.0749, and 1.0151, when the viscosity of water is unity.

According to C. L. Parsons, the anhydrous sulphate is stable in dry air; so also is the dihydrate. According to L. F. Nilson and O. Pettersson, the crystals of the tetrahydrate are stable in dry air, but J. Weeren found that they effloresce in dry air at ordinary temp., and also, according to H. Debray, in warm dry air. C. L. Parsons found the **vapour pressure** of the tetrahydrate at 20° is equal to the press. of 20 mm. of olive oil, and increases rapidly on a rising temp.; the tetrahydrate gradually loses water of crystallization when confined over phosphorus pentoxide, and J. Weeren found the crystals lose one-third their water of crystallization at 35°. According to A. Atterberg, the tetrahydrate loses the eq. of two mols of water at 100°; at 150°, another mol of water is lost; and all is given off at 180°. L. F. Nilson and O. Pettersson found that the tetrahydrate loses two mols of water between 100° and 110°, and the rest at 250°. G. Krüss and H. Moraht also stated that all the combined water is lost at 250°. According to A. von Awdejef, and H. Debray, the tetrahydrate first loses water, and when heated more strongly, it loses sulphur trioxide, as sulphur dioxide and oxygen, and beryllium oxide remains. J. Weeren found that no sulphur trioxide is lost at 200°. G. Marchal found the thermal decomposition between 590° and 830° corresponds with $\text{BeSO}_4 = \text{BeO} + \text{SO}_3$,

and $2\text{SO}_3 \rightleftharpoons 2\text{SO}_2 + \text{O}_2$; and $\log p = -14907T^{-1} - 14.1 \log T + 57.97$, where p denotes the partial press. of sulphur trioxide. The computed **heat of dissociation** is -53.5 cals.

According to C. L. Parsons, also, when anhydrous beryllium sulphate is heated, it begins to lose sulphur trioxide at about 400° , and as J. J. Berzelius found the decomposition is complete at a white heat. The **melting point** of the dihydrate in a sealed tube is 145° , and the molten salt boils at 150° . M. Levi-Malvano found the tetrahydrate partially melts in its water of crystallization if rapidly heated to 110° , and begins to bubble and boil. At 125° , the mass again becomes dry. The hexahydrate was found by M. Levi-Malvano to melt at 78.8° , with the separation of a mass of crystals which later pass into soln.; on cooling, the liquid freezes at 67° , and the temp. then rises to 68.4° . According to L. F. Nilson and O. Pettersson, the **specific heat** of anhydrous beryllium sulphate is 0.1978 . J. Thomsen found the **heat of solution** of a mol of the tetrahydrate in 400 mols of water to be 1.10 Cals.; J. H. Pollok found 0.85 Cal. For the **heat of formation** from beryllium hydroxide and sulphuric acid, *vide supra*.

According to H. Töpsöe and C. Christiansen, the tetragonal crystals of tetrahydrated beryllium sulphate are uniaxial, optically negative, and doubly refracting. The **indices of refraction**, μ , of the tetrahydrate, averaged from measurements by G. Wulff, and H. Töpsöe and C. Christiansen, are:

	Ordinary ray.			Extraordinary ray.		
	C	D	F	C	D	F lines
μ . . .	1.4688	1.4717	1.4774	1.4336	1.4358	1.4408

J. H. Gladstone and W. Hibbert give 47.41 for the **molecular refraction** of the solid sulphate, and 47.94 for the same salt in aq. soln. H. Jahn found the **specific rotation** to be 0.28895 , and the mol. electromagnetic rotation of the plane of polarization in soln. to be 1.83 (water unity). H. Ley found the eq. **electrical conductivity**, λ , of soln. with a mol of beryllium sulphate in v litres of water, at 25° , to be

v . . .	32	64	128	256	512	1024
λ . . .	66.4	77.0	88.7	99.4	112.6	124.4

Both H. Ley, and L. Bruner found that beryllium sulphate is hydrolyzed in soln., but the percentage **hydrolysis** is less than with soln. of aluminium and ferric sulphates; the latter estimates that at 40° , $\frac{1}{4}N$ -, $\frac{1}{2}N$ -, and $\frac{3}{4}N$ -soln. are hydrolyzed respectively 0.52 , 0.58 , and 0.68 per cent. The aq. soln. of beryllium sulphate is strongly acid to indicators; it attacks zinc with the evolution of hydrogen; liberates carbon dioxide from carbonates; and dissolves a relatively large proportion of beryllium hydroxide or carbonate—evolving carbon dioxide in the latter instance, all of which indicate a high conc. of the hydrogen ions or free acid, although C. L. Parsons has shown that a very small excess of base completely inhibits the power to invert cane sugar. The taste of the salt appears to be both acid and sweet. R. Höber and F. Kiesow found that the sulphate and chloride have the same sweet taste at equal ionic conc. According to S. Meyer, the **magnetic susceptibility** at 18° of anhydrous beryllium sulphate is -0.326×10^{-6} units; and of the tetrahydrate at 17° -0.314×10^{-6} units per grm. or -0.071×10^{-6} units per mol. A. Cossa and D. Pecile found beryllium sulphate reacts with magnesium fluoride, forming beryllium fluoride.

The basic sulphates of beryllium.—J. J. Berzelius³ showed that a soln. of beryllium sulphate can dissolve its own hydroxide, and, guided by the law of definite proportions, he assigned formulæ, $3\text{BeO} \cdot \text{SO}_3 \cdot 4\text{H}_2\text{O}$ and $2\text{BeO} \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$, to the evaporated gummy residues of the corresponding soln. merely because they represented whole eq. although he must have obtained residues with intermediate proportions; he also assigned the formula $9\text{BeO} \cdot \text{SO}_3 \cdot 14\text{H}_2\text{O}$ to the basic precipitate obtained by diluting the conc. soln. of $\text{BeSO}_4 + 2\text{Be}(\text{OH})_2$. In 1854, H. Debray employed the basic sulphates as a method of separating beryllium from aluminium,

but he assigned no formulæ to the basic sulphates. By diluting a conc. soln. of beryllium sulphate, sat. with beryllium hydroxide, A. Atterberg also obtained a precipitate to which he assigned formulæ, $\text{BeSO}_4 \cdot 5\text{Be}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$ and $\text{BeSO}_4 \cdot 7\text{Be}(\text{OH})_2 \cdot \text{H}_2\text{O}$. He also evaporated soln. containing two and three eq. of the oxide to one of acid, and obtained *residua* corresponding with the formulæ given by J. J. Berzelius.

C. L. Parsons showed that the quantities of hydroxide or carbonate dissolved are proportional to the conc. of the soln. of the beryllium salt, but the proportionality is not so apparent with dil. soln. A variation in the acid radicle determines the solubility thus—the sulphate can dissolve three eq. of beryllium oxide to one of sulphate, the chloride can dissolve four eq., and, as J. M. Ordway showed, the acetate can dissolve six eq. The dilution of these soln. with water furnishes non-crystallizable highly basic precipitates; the evaporation of the soln. leaves a gummy residue. The dried precipitates and evaporation *residua* are non-crystalline and glassy, they vary in composition with the conc. of the soln. from which they are derived, and the extent to which the acid dissolved the base. By diluting the more basic soln. of beryllium sulphate C. L. Parsons indeed obtained precipitates with $\text{BeO} : \text{SO}_3$ as 25 : 1. When the precipitates are washed they become more and more basic, and finally approach the composition of the hydroxide, although the last trace of acid cannot be removed by washing. The evaporation of the mother liquid remaining after the separation of a precipitate also furnishes non-crystalline and glassy masses which are physically indistinguishable from the basic precipitates except that they are soluble in water.

C. L. Parsons, W. O. Robinson, and C. T. Fuller found that the f.p. of soln. of beryllium sulphate is raised by beryllium hydroxide, and they concluded that there is a compound formed between the normal sulphate and hydroxide giving a smaller number of effective osmotic parts; or there is an aggregation of the dissolved molecules; or the hydroxide is colloidal in its nature and interferes with the free movement of the crystalloid particles. Attempts to precipitate a soluble basic sulphate by the addition of electrolytes gave negative results. When the soln. are dialyzed, the membrane has a tendency to separate the excess of base from the normal salt, but no such separation occurs when the normal sulphate is dialyzed. The electrolysis of the soln. and measurements of the transport of the ions show that no complex anion containing beryllium is formed. The dissolution of hydroxide by soln. of the normal sulphate lowers the electrical conductivity.

It is therefore inferred that when beryllium hydroxide dissolves in a soln. of one of its normal salts, there is no evidence of the formation of a molecular complex, or of a colloidal soln. C. L. Parsons stated that the soln. of the beryllium salt acts as a solvent for beryllium hydroxide in a manner exactly analogous with the dissolution of camphor by acetic acid. It is also concluded that the so-called basic beryllium sulphates do not exist as separate and definite chemical compounds, but are in reality solid soln. of the hydroxide and sulphate, which are much more basic in composition when equilibrium with the mother liquors is reached than when first precipitated. The truly basic compounds of beryllium so far obtained, which are crystalline and of a definite composition, belong solely to the fatty acid series.

A number of hydrated double sulphates of beryllium has been prepared, but they have not all been tested by phase-rule criteria. L. N. Vauquelin⁴ probably made a dihydrated **potassium beryllium sulphate**, $\text{BeSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and the salt was described by A. von Awdejef, and subsequently by H. Debray, J. C. G. de Marignac, etc. It is made by the evaporation of a soln. of eq. proportions of the component salts. The crystals are colourless and so ill-defined that J. C. G. de Marignac was unable to determine their form. A. von Awdejef found that they are much more soluble in hot than in cold water, and, according to A. Atterberg, they lose all their water of crystallization at 100° . G. Klatzo claimed that the crystals which separated at -2° or -3° are trihydrated, $\text{K}_2\text{SO}_4 \cdot \text{BeSO}_4 \cdot 3\text{H}_2\text{O}$. W. Grahmann found that potassium and beryllium sulphates form a single compound in tetragonal

crystals, potassium beryllium trisulphate, $K_2SO_4 \cdot 2BeSO_4$, with a maximum on the f.p. curve at about 910° —Fig. 5. Solid soln. are not formed. H. T. S. Britton and A. J. Allmand studied the ternary system K_2SO_4 — $BeSO_4$ — H_2O at 25° , and obtained the results summarized in Fig. 6, the only complex observed was L. N. Vauquelin's

FIG. 5.—Freezing-point Curves of Binary Mixtures of K_2SO_4 — $BeSO_4$.

FIG. 6.—Solubility Curves of Mixtures of K_2SO_4 — $BeSO_4$ in Water at 25° .

salt, $K_2SO_4 \cdot BeSO_4 \cdot 2H_2O$. H. Debray precipitated tetrahydrated **potassium beryllium hydrosulphate**, $2K_2O \cdot BeO \cdot 4SO_3 \cdot 5H_2O$, or $BeSO_4 \cdot K_2SO_4 \cdot 2KHSO_4 \cdot 4H_2O$, by adding dil. sulphuric acid to a mixed soln. of the component salts; and A. Atterberg evaporated a strongly acid soln. of eq. proportions of the component salts. The fine acicular prisms lose 11.75 per cent. (3 mols) water at 100° , and 3.31 per cent. (one mol) more at 300° ; at a dull red heat, one-fourth of the sulphur trioxide is lost. A. Atterberg prepared radiating star-shaped groups of fine acicular crystals of dodecahydrated **sodium beryllium sulphate**, $2Na_2SO_4 \cdot 3BeSO_4 \cdot 12H_2O$, by evaporating to a thick syrup, a soln. of at least three mols of beryllium sulphate to one mol of sodium sulphate. The crystals are stable in air. A. Atterberg also prepared crystals of dihydrated **ammonium beryllium sulphate**, $BeSO_4 \cdot (NH_4)_2SO_4 \cdot 2H_2O$, from the syrupy liquid obtained by evaporating a soln. of the component salts on a water-bath, and then over conc. sulphuric acid. The crystals lost all their water at 100° . H. T. S. Britton's study of the ternary system: $BeSO_4$ — $(NH_4)_2SO_4$ — H_2O at 25° , Fig. 7, showed that this is the only double salt stable under these conditions. G. Klatzo claimed to have made tetragonal crystals of **beryllium cupric sulphate**, $Be_4Cu(SO_4)_5 \cdot 20H_2O$, isomorphous with tetrahydrated beryllium sulphate by adding an excess of beryllium sulphate to an acid soln. of the cupric salt; and triclinic crystals of $BeCu_9(SO_4)_{10} \cdot 50H_2O$, by keeping the cupric salt in excess; but, according to J. C. G. de Marignac, beryllium cupric sulphate cannot be obtained, and J. W. Retgers found that the component salts do not form isomorphous mixtures.

§ 12. Beryllium or Glucinum Carbonate

L. N. Vauquelin noticed that beryllium hydroxide readily attracts carbon dioxide from the air; and he noted the solubility, in soln. of alkali or ammonium carbonate, of the precipitate obtained by adding an aq. soln. of ammonium carbonate to a soln. of beryllium hydroxide; and J. J. Berzelius noted the solubility of the precipitate in soln. of other ammonium salts. Normal beryllium carbonate, BeCO_3 , is not known. G. Klatzo¹ claimed to have made small crystalline masses of the tetrahydrate, $\text{BeCO}_3 \cdot 4\text{H}_2\text{O}$, by passing carbon dioxide into water with beryllium hydroxide in suspension, filtering, and evaporating in an atm. of carbon dioxide. He further stated that the product loses its water and one-sixth of its carbon dioxide at 100° , and half the carbon dioxide at 200° . There is, however, some mistake because the carbonate is so readily hydrolyzed by water that in aq. soln. the product is always a basic beryllium carbonate, or beryllium oxycarbonate. Similar results are obtained when a soln. of a beryllium salt is precipitated with sodium or potassium carbonate, or when a soln. of beryllium hydroxide in one of ammonium carbonate, or sodium hydrocarbonate, is boiled; chemically, the basic precipitate is much the same, whether it is precipitated by the addition of a soluble carbonate, or by boiling an ammonium carbonate or dil. sodium hydrocarbonate soln. In either case, notable quantities of the precipitant are occluded, and are not all removed by washing. F. von Schaffgotsch found the basic carbonate precipitated by ammonium carbonate was not free from the double ammonium beryllium carbonate.

According to C. L. Parsons, occluded ammonia can be removed by prolonged boiling or by intermittently passing carbon dioxide through the precipitate suspended in water, filtering off the liquid and repeating. Many hours' boiling is required by the first procedure, and the residue left is almost the pure hydroxide, while if the second method is used the purification is a matter of days, but the residue is about as rich in the CO_2 component as when first precipitated. Passing carbon dioxide through the boiling liquid has little effect on the result as would naturally be expected. The ammonia may be removed with but little loss of carbon dioxide, by momentarily boiling with steam, filtering, adding fresh cold water, and repeating the operation several times. Ordinary washing with hot water does not seem to be effective. Drying at 100° does not remove the occluded ammonia, but its odour becomes immediately apparent on heating to the point where the carbon dioxide begins to be evolved.

A number of different formulæ has been reported for the basic carbonate. The proportions, $\text{BeCO}_3 : \text{Be(OH)}_2 : \text{H}_2\text{O}$, were represented by F. von Schaffgotsch as 2 : 7 : 2; by J. Weeren as 2 : 7 : 3 and 4 : 8 : 5; by H. Debray, and by G. Klatzo as 1 : 2 : 3; by T. Parkmann as 1 : 2 : x ; by K. Seubert and M. Elten as 1 : 5 : 3; and by J. H. Pollok as 1 : 2 : 2. There is here nothing to indicate that any one of these formulæ represents a chemical individual.

These reports of the composition of the basic carbonates obtained under various conditions, are themselves evidence that the different basic carbonates are merely different stages in a slow process of approach to a yet unknown condition of equilibrium in the ternary system $\text{BeO}-\text{CO}_2-\text{H}_2\text{O}$. According to C. L. Parsons, "in the presence of the largest possible amount of carbon dioxide, the composition approximates to 1 : 2 : x , but boiling not only increases the hydrolysis, but removes carbon dioxide from the system, and slowly causes the solid phases to approach the pure hydroxide." According to F. von Schaffgotsch, the precipitate obtained by using an alkali carbonate is gelatinous and difficult to wash; and, according to J. J. Berzelius, that obtained by boiling an ammonium carbonate soln. is granular and filters easily. According to J. H. Pollok, a litre of a sat. soln. of ammonium carbonate dissolves an amount of freshly precipitated beryllium carbonate or hydroxide eq. to 22 grms. beryllia; and when this soln. is boiled, carbon dioxide and ammonia escape, and the white granular basic carbonate precipitate begins to appear. According to C. L. Parsons, the boiling is best done by blowing in steam, otherwise violent bumping takes place, which is not altogether prevented by continuous stirring. The basic carbonate varies in composition as the precipitation progresses; for example, the first portions precipitated under these conditions are richer in carbon dioxide than the later precipitate, which, according to K. Seubert and M. Elten, has the composition 1 : 5 : 3; and if the boiling is continued until precipitation is complete, C. L. Parsons found the composition approximates to 1 : 3 : 2 (when dried over sulphuric acid); on the other hand, if the soln. be diluted more hydrolysis occurs with less boiling, and the composition of the precipitate approximates to 1 : 2 : x . This product can be dried at 150° without loss of carbon dioxide. If the boiling be continued, carbon dioxide is gradually lost, and the product approximates to that of the hydroxide. C. L. Parsons attempted to increase the carbon dioxide component by passing the gas under press. over the fresh precipitate, and over the freshly precipitated hydroxide, but without success. P. N. Raikow found that freshly precipitated beryllium hydroxide absorbs enough carbon dioxide to form $\text{BeCO}_3 \cdot 3\text{Be(OH)}_2$, and F. K. Cameron and W. O. Robinson measured the vap. press. of carbon dioxide over wet beryllium hydroxide at 0° , and found a slight absorption of carbon dioxide, but no evidence of the formation of a definite carbonate. The vap. press. curve in cm. of mercury approximates to a straight line:

Grms. CO_2 added . . .	0.000	0.014	0.084	0.126	0.182	0.238	0.252
Vap. press.	76	87	101	205	271	330	346

The basic carbonate precipitated from boiling ammonium carbonate soln. has no definite composition, but it is a convenient source for the preparation of beryllium salts because it readily dissolves in acids, and if the occluded ammonia be removed, the salts are of a high degree of purity. The substitution of sodium hydrocarbonate

for ammonium carbonate gives a precipitate less readily obtained in a granular form, and contaminated with adsorbed sodium carbonate. Both precipitates may be contaminated with a little alumina if such be present in the system. S. Meyer gave $+0.099 \times 10^{-6}$ units per grm. or 0.017×10^{-6} units per mol for the magnetic susceptibility of what he regarded as BeCO_3 ; and -0.050×10^{-6} units per grm. or -0.030×10^{-6} units per mol for what he regarded as $\text{BeCO}_3 \cdot \text{BeO}$.

An aq. soln. of sodium carbonate was found by F. von Schaffgotsch to dissolve beryllium carbonate; if beryllia be fused with an excess of sodium carbonate, between 8.7 and 9.5 per cent. of carbon dioxide is expelled in $1\frac{1}{2}$ hrs., and when extracted with water, about 77.8 per cent. of beryllia remains undissolved; that which passes into soln. is gradually precipitated by the action of atm. carbon dioxide. C. G. Gmelin found beryllium carbonate is dissolved by an aq. soln. of potassium carbonate, but beryllia precipitated from a boiling soln. of potassium hydroxide, and, according to F. von Schaffgotsch, ignited beryllia are not soluble in that menstruum. If a soln. of beryllium and potassium carbonates be boiled until the precipitate begins to form, and alcohol be then added, H. Debray found a **potassium beryllium carbonate** to which he assigned the formula $3\text{K}_2\text{Be}(\text{CO}_3)_2$. $\text{Be}(\text{OH})_2$ is precipitated; it was also obtained as a white precipitate by adding alcohol to a soln. of beryllium hydroxide in potassium carbonate. If an ammonium carbonate soln. of beryllium hydroxide be treated with alcohol, the white precipitate which forms is fairly stable, and its composition depends on the relative masses of the component salts. H. Debray obtained **ammonium beryllium carbonate** by a similar process to that described for the potassium salt. The composition of the precipitate is $3(\text{NH}_4)_2\text{Be}(\text{CO}_3)_2 \cdot \text{Be}(\text{OH})_2$, according to H. Debray, and G. Klatzo, while T. S. Humpidge assigns the formula $2(\text{NH}_4)_2\text{Be}(\text{CO}_3)_2 \cdot \text{Be}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$. The product loses ammonia and carbon dioxide, slowly in the cold, but rapidly when heated.

§ 13. Beryllium or Glucinum Nitrate

L. N. Vauquelin¹ obtained **beryllium nitrate** as an uncrystallizable elastic mass by evaporating a soln. of the hydroxide or carbonate in nitric acid. J. F. Gmelin made a similar observation as to the extreme difficulty in crystallizing the nitrate. J. M. Ordway precipitated a soln. of beryllium sulphate with barium nitrate, and evaporated the soln. over sulphuric acid. The resulting solid approached the normal trihydrated nitrate in composition, $\text{Be}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, but was still basic, as must necessarily occur when the salt is prepared in the presence of water in quantity. The commercial nitrate smells strongly of nitric anhydride. The aq. soln. is strongly acidic. H. Ley, and L. Bruner found that soln. with a gram-eq. per 10, 20, and 40 litres were respectively hydrolyzed 1.8, 1.8, and 1.9 per cent. at 40° . J. M. Ordway remarked on the readiness with which the nitrate loses water; at 100° , for example, its composition approximates to $2\text{Be}(\text{NO}_3)_2 \cdot \text{BeO}$. C. L. Parsons also found that by

evaporating an aq. soln. of the nitrate, it becomes strongly basic below 50°. A. Atterberg did not succeed in making the nitrate.

According to C. L. Parsons, crystals of **tetrahydrated beryllium nitrate**, $\text{Be}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, are easily made by saturating nitric acid with basic beryllium carbonate, evaporating to a syrupy consistency, adding conc. nitric acid in excess, and crystallizing therefrom. He added that "the crystals are highly deliquescent; they readily lose nitric anhydride, for they are stable only in the presence of conc. nitric acid, or in equilibrium with its vapour; and they melt in their own water of crystallization at 60.5°"; J. M. Ordway gave 60° for the m.p. and added that the molten liquid can be under-cooled to 34°, when it crystallizes, during which the temp. rises rapidly to about 58°. According to C. L. Parsons, the molten liquid immediately begins to give off bubbles of gas, and on raising the temp., "nitric anhydride is rapidly evolved leaving behind a viscous mass readily soluble in water when it has reached the tribasic condition. Even below 175°, it has become tetra-basic, and loses all its nitric anhydride below a red heat." He found another sample lost about 75 per cent. of its nitric anhydride when dried below 175°; and C. A. Joy found that all the nitric anhydride is evolved between 200° and 250°. C. L. Parsons found that the oxide prepared by heating the nitrate contains "a small amount of occluded oxygen and nitrogen, which, if the decomposition has been gradually brought about, is eq. approximately to 0.35 c.c. of mixed gases, of which approximately two-thirds are nitrogen, per gram of oxide." According to J. C. G. de Marignac, beryllium nitrate gives no mixed crystals with magnesium, lanthanum, or didymium nitrates. K. Jauch found the sp. ht. of *N*-soln. of beryllium nitrate at 18°:

<i>N</i>	.	.	0.5	1.0	2.0	3.0	4.0
Sp. ht.	.	.	0.9619	0.9287	0.8928	0.8443	0.7966

A. Heydweiller has measured the sp. gr., *D*, and equivalent conductivities, λ , of sol. containing *m* eq. per litre, when δD denotes the values of $(D-1)10^4$ reduced to a vacuum.

<i>m</i>	.	.	0.5	1.0	2.0	3.0	4.0	5.0
δD	.	.	202.4	400.9	800	1197	1592	1984
λ	.	.	63.8	56.2	45.8	37.5	30.84	24.85

According to C. L. Parsons, beryllium nitrate is insoluble in alcohol and acetone. Beryllium nitrate has been employed as a hardening agent in the manufacture of incandescent mantles.

J. M. Ordway prepared two of what he regarded as **basic beryllium nitrates**, or **beryllium oxynitrate**, the one, $3\text{BeO} \cdot 2\text{N}_2\text{O}_5$, or $2\text{Be}(\text{NO}_3)_2 \cdot \text{BeO}$, by adding beryllium hydroxide, or aq. ammonia to a soln. of the normal nitrate; and the other, $2\text{BeO} \cdot \text{N}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or $\text{Be}(\text{NO}_3)_2 \cdot \text{BeO} \cdot 3\text{H}_2\text{O}$, by heating the normal nitrate 20 hrs. on a water-bath, or by adding beryllium carbonate to a soln. of the normal nitrate in eq. proportions. C. L. Parsons added that it is extremely doubtful if these basic nitrates are chemical compounds, but they are rather solid soln. of the normal salt and the hydroxide, or of the hydroxide with more or less occluded normal salt.

§ 14. Beryllium or Glucinum Phosphates

The chemistry of the beryllium phosphates is not satisfactory. Comparatively few workers have studied these compounds, and the products they have described are of a gelatinous or colloidal nature, and therefore difficult to identify. It is doubtful if the normal phosphate, free from the products of hydrolysis, has been made. In 1798 L. N. Vauquelin¹ obtained a white viscid precipitate by adding an excess of disodium hydrophosphate to a soln. of a beryllium salt. The precipitate fused to a clear transparent glass, which was insoluble in water, but soluble in acids, including phosphoric acid. A. Atterberg employed the same process as L. N. Vauquelin, and obtained a white voluminous powder which he regarded as heptahydrated **beryllium orthophosphate**, $\text{Be}_3(\text{PO}_4)_2 \cdot 7\text{H}_2\text{O}$; he stated that when the heptahydrate is dried at 100° nearly four mols of water were evolved, leaving behind $\text{Be}_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$, and he added that the product does not melt at a red heat. The phosphate dissolved in nitric acid, and, when the free acid was neutralized with ammonia, the phosphate with less combined water, was re-precipitated by treatment with sodium acetate. B. Bleyer and B. Müller obtained the hexahydrate, $\text{Be}_3(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$, by mixing acetic acid soln. of disodium hydrophosphate and beryllium sulphate; and by using normal sodium phosphate, they obtained a basic salt—**beryllium hemioxyorthophosphate**, $\text{BeO} \cdot 2\text{Be}_3(\text{PO}_4)_2 \cdot 13\text{H}_2\text{O}$. F. Sestini obtained a crystalline product to which he assigned the formula $\text{Be}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$, by dissolving Vauquelin's precipitate in 10 per cent acetic acid, and boiling the filtered soln. It lost one mol of water at 100° , and the resulting $\text{Be}_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$ lost the remaining water at a higher temp. Sestini's phosphate dissolved in water rather more readily than aluminium phosphate; a litre of 2 per cent. acetic acid dissolved 0.55 grm., and a litre of 10 per cent. acetic acid, 1.725 grms.; the ratio $\text{BeO} : \text{H}_3\text{PO}_4$ in the soln. is the same as in the undissolved portion; and if the soln. be heated, a basic phosphate is precipitated. H. Grandeau found that beryllium and aluminium phosphates behave in a similar manner when heated with alkali sulphate—*vide infra*. G. Scheffer also obtained crystals of what he regarded as a hydrated **beryllium nitratophosphate** by concentrating a soln. of beryllium phosphate in nitric acid.

By adding alcohol to a soln. of beryllium hydroxide in phosphoric acid, A. Atterberg obtained a viscous precipitate, which gradually hardened, and to which he assigned the composition $2\text{BeO} \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, this corresponding with trihydrated **beryllium hydrophosphate**, $\text{BeHPO}_4 \cdot 3\text{H}_2\text{O}$. G. Scheffer also obtained a product with a similar composition, but with less water, by adding an aq. soln. of disodium hydrophosphate to one of beryllium nitrate at 150° . B. Bleyer and B. Müller could not get the trihydrate free from adhering phosphoric acid. They prepared **beryllium dihydrophosphate**, $\text{Be}(\text{H}_2\text{PO}_4)_2$, from the hydroxide and orthophosphoric acid, in colourless hygroscopic leaflets. G. Scheffer obtained what he regarded as pentahydrated **beryllium pyrophosphate**, $\text{Be}_2\text{P}_2\text{O}_7 \cdot 5\text{H}_2\text{O}$, as a white pulverulent precipitate, by adding a soln. of normal sodium pyrophosphate to one of beryllium nitrate. B. Bleyer and B. Müller gave $\text{Be}_2\text{P}_2\text{O}_7 \cdot 9\text{H}_2\text{O}$ for the composition of the precipitate from sodium pyrophosphate; they also obtained colourless crystals of **beryllium metaphosphate**, $\text{Be}(\text{PO}_4)_2$. This salt must be prepared in the absence of water, or a basic salt is formed.

According to the analysis of E. S. Dana and H. L. Wells, the secondary mineral, **beryllonite**, at Stoneham (Maine), has a composition corresponding with **sodium beryllium orthophosphate**, NaBePO_4 . It was prepared in hexagonal plates, by K. A. Wallroth, by slowly cooling a fused mixture of beryllium oxide in sodium metaphosphate and extracting the mass with water or dil. hydrochloric acid—beryllonite remains as a sparingly soluble residue. L. Ouvrard also made it in a similar way by using sodium pyrophosphate in place of the metaphosphate; he found that if normal phosphate is used, plates of **tetrasodium beryllium diphosphate** are formed: $\text{Na}_4\text{Be}(\text{PO}_4)_2$, or $\text{Na}_3\text{PO}_4 \cdot \text{NaBePO}_4$. According to E. S. Dana, native

sodium beryllium phosphate, NaBePO_4 , forms rhombic bipyramids, with axial ratios $a:b:c=0.57243:1:0.54901$, and sp. gr. 2.845 at 20° ; L. Ouvrard's crystals had a sp. gr. 2.72. The hardness of the mineral is $5\frac{1}{2}$ to 6 on Mohs' scale. The double refraction is negative, and the refractive indices for Na-light are $\mu_a=1.5520$; $\mu_\beta=1.5579$; and $\mu=1.5608$. According to K. A. Wallroth, the salt is sparingly soluble in cold acids, but easily soluble in warm acids; it is insoluble in acetic acid. Beryllonite fuses rather easily. B. Bleyer and B. Müller say that they could make sodium beryllium orthophosphate only as a precipitate of variable composition. J. Persoz stated, without giving details, that he made **alkali beryllium pyrophosphates**. According to A. Atterberg, a soln. of sodium pyrophosphate dissolves beryllium pyrophosphate; and when sodium pyrophosphate is added to a soln. of beryllium sulphate, a precipitate appears when about three-fourths of the necessary quantity of the sodium salt has been added for complete decomposition, and a gelatinous mass is finally formed. B. Bleyer and B. Müller made **sodium beryllium pyrophosphate**, $\text{Be}_2\text{P}_2\text{O}_7 \cdot 2\text{Na}_4\text{P}_2\text{O}_7 \cdot 5\text{H}_2\text{O}$, as a soluble hygroscopic salt.

H. Grandeau first prepared **potassium beryllium orthophosphate**, KBePO_4 , by fusing beryllium sulphate with twenty-five times its weight of potassium phosphate between 800° and 1000° ; at a higher temp. the phosphate is decomposed. The cold mass is extracted with water and rhombic prismatic acicular crystals of the double salt remain. L. Ouvrard also found rhombic prisms of the same salt are formed by fusing beryllium oxide with potassium meta-, pyro-, or ortho-phosphate. B. Bleyer and B. Müller could make potassium or ammonium beryllium orthophosphate only as precipitates of variable composition. According to C. Rössler, a crystalline precipitate of **ammonium beryllium phosphate**, similar to ammonium magnesium phosphate is produced when an excess of ammonium phosphate is added to a soln. of a beryllium salt, and the precipitate dissolved in hydrochloric acid, neutralized with aq. ammonia, and boiled. The precipitate is crystalline, and settles quickly. It is insoluble in cold water, sparingly soluble in hot water. The precipitate has a variable composition. When calcined, it loses ammonia and water, and forms beryllium pyrophosphate. M. Austin concluded that this is not an accurate way of quantitatively determining beryllium. G. Scheffer obtained a white granular precipitate of the triple salt **ammonium sodium beryllium orthophosphate**, $(\text{NH}_4)_2\text{O} \cdot \text{Na}_2\text{O} \cdot \text{BeO} \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, or $(\text{NH}_4)_2\text{Na}_2\text{Be}(\text{PO}_4)_2 \cdot 7\text{H}_2\text{O}$, by adding disodium hydrophosphate to a soln. of beryllium nitrate, mixed with sodium chloride.

W. Haidinger² described a mineral which was found at the mines of Ehrenfriedersdorf, Saxony, and called **herderite**—after Brown Herder. A. Breithaupt called it *allogonite*; W. E. Hidden found a deposit at Stoneham, Maine, and called it *glucinite*. Analyses were reported by J. B. Mackintosh, C. Winkler, F. A. Genth, and S. L. Penfield and D. N. Harper. The results show that herderite is a **calcium beryllium fluo-orthophosphate**, $(\text{CaF})\text{BePO}_4$, or rather $\text{Ca}(\text{BeF})\text{PO}_4$, in which more or less of the fluorine may be replaced by hydroxyl. The member at the other end of the series is *hydro-herderite*, $\text{Ca}(\text{BeOH})\text{PO}_4$. The crystals were examined by W. Haidinger, A. des Cloizeaux, W. E. Hidden, and E. Bertrand; they belong to the rhombic system, and have the axial ratios $a:b:c=0.62060:1:0.42345$. The optic axial angles are $2E=120^\circ 33'$ to $121^\circ 44'$; $2H_a=71^\circ 24'$ to $70^\circ 34'$; $2H_0=105^\circ 11'$ to $105^\circ 23'$; and $2V=74^\circ 16'$ to $74^\circ 29'$. The indices of refraction for Na-light are $\alpha=1.592$, $\beta=1.612$, and $\gamma=1.621$. The optical character is negative. The sp. gr. ranges from 2.99 to 3.012; and the hardness is 5.

CHAPTER XXIX

MAGNESIUM

§ 1. The History of Magnesium

IN 1695, N. Grew examined the mineral water of Epsom, and, in his *Tractatus de salis cathartici amari in aquis Ebeshamensibus ei hujusmodi aliis contenti natura et usu* (London, 1695), he reported his discovery of magnesium sulphate. The medicinal virtues of this salt soon afterwards became widely known, and it came to be called *Epsom salts*, *sal anglicum*, *English salts*, *sal catharticum*, *bitter salt*, etc. The presence of the same substance was detected in other mineral springs, and in 1700, G. and F. Moulton established a works for extracting the salt from the waters of a spring at Shooter's Hill, near London. H. Kopp¹ says that in 1710, Mr. Hoy discovered that the same salt could be extracted from the mother liquor remaining after the evaporation of sea-water. Ferrous sulphate (colcothar of vitriol) was added, and crystallizable "bitter salt" was produced. In 1717, F. Hoffmann showed that the salt was present in the mineral waters of Seidlitz, and that derived from this source was called *Seidlitz salt*; others soon found the salt in the waters from numerous other springs.

About this time, too, T. Bergman told us, in his essay *De magnesia* (Upsala, 1775), that Count di Palma, a citizen of Rome, prepared a white powder which he claimed was a panacea for all diseases; and he induced an ecclesiastic of the Church to dispose of it for him. The powder was called *magnesia alba* or *Count Palma's powder*; and its nature was solicitously concealed as a profound secret, until M. B. Valentini disclosed the method of preparation in his *Relatio de magnesia alba, novo, genuino, polychresto et innixio pharmaco purgante Roma nuper advecto* (Giessa Hassorum, 1707), namely, by calcining the residue remaining after evaporating to dryness the mother liquor from the preparation of nitre. We are also told that two years later J. H. Slevogt² showed how *magnesia alba* could be more easily obtained by precipitation from the mother liquors by treating them with a fixed alkali. Works by B. J. Lembeck,³ H. Smith, S. Glass, D. Ingram, J. Schaeffer, C. Norell, P. J. Macquer, and T. Henry are of historical interest.

It is not known why the name *magnesia alba* was given to the product in contrast with *magnesia nigra*, as the black oxide of manganese was then called. Dioscorides used the terms μάγνης λίθος or μάγνης, and Pliny *magnes*, for magnetic iron ore and pyrolusite. According to the latter:

It received its name *magnes*, Nicander informs us, from the person who was the first to discover it upon Ida. (Isodorus, in his *Origines*, said India.) It is said that Magnes made this discovery when, upon taking his herds to pasture, he found that the nails of his shoes and the iron ferrule of his staff adhered to the ground.

Others refer the terms to the place where the stone was found—e.g. *Magnesia* in Asia. Pliny distinguished between what he called the male and female sex of *magnes*—*magnes qui niger est feminei sexus ideoque sine viribus*, and he described five different kinds of *magnes*, all but one of which were nearly black. The *magnes* from *Magnesia* in Asia was said to be white, and to resemble pumice in appearance, but to have no attractive influence on iron. From the early writings it is evident that at least three minerals of a totally different nature were called *magnesia*—(i) *magnesium lapis*, which is now represented by magnetite, was magnetic;

(ii) *magnesia nigra*, which is now represented by pyrolusite; and (iii) a silver-white mineral, which could be conveniently fashioned in a lathe, or easily shaped and carved with hand tools, and it is probably now represented by steatite.

The alchemists used the word *magnesia* in a number of different senses. It was their custom to appropriate common terms and give special meanings associated with their mystical notions. Thus A. E. Waite⁴ says:

Magnesia was at different times the matter, red or white, of the philosopher's stone; something like common mercury, of celestial and transcendent brightness; neither animal, vegetable, nor mineral; resembling a stone but not a stone; white gum; water of the sea; water of life; child of the elements; a pure virgin; a secret celestial spirit, neither thick nor thin, not wholly earthy nor wholly igneous, but a mean aerial substance, to be found everywhere and at all seasons.

J. Beckmann has said that the term *manganese* is a corruption of the word *magnesia*, and that it was first used by Albertus Magnus who, in his *De mineralibus*, wrote the name of the magnet in at least five different ways: *magnesia*, *magnasia*, *magnosia*, *mangadesum*, and *manganensis*. The difference between *magnesia nigra* and the magnetic ore was demonstrated towards the middle of the eighteenth century. At the beginning of that century Count di Palma's powder appeared, and the French, English, and Italians soon afterwards employed the term *manganès* for the black mineral and *magnesia* for the white. Thus, in the sixteenth century, C. Leonard,⁵ M. Mercati, and H. Cardan employed the term *manganès* for *magnesia nigra*, although metallic manganese was not discovered until the eighteenth.

F. Hoffmann, in his *Dissertationum physico-chymicarum* (Halæ Magdeburgicæ, 1729), first demonstrated the individuality of *magnesia* which had long been confounded with lime. Speaking of Epsom salts, he said:

There are a great number of waters—among which may be cited those of Eger, Elster, Schwalbach, and Wildung—containing a neutral salt which has not yet received a name, and which is almost unknown. I have found it in the waters of Hornhausen, which owe to this salt their aperitive and diuretic properties. It is commonly called *nitrum*, but it has none of the characters of nitre—e.g. it is not inflammable, its crystalline form is different, and it does not give aqua fortis like nitre does. It is a neutral salt resembling *arcanum duplicatum* (potassium sulphate), its taste is bitter, and it produces with the tongue a sensation of cold; it effervesces neither with acids nor alkalies, and is not very fusible. . . . This salt appears to have been formed *ex combinatione acidi sulphurei et calcaria terra* of an alkaline nature.

A few years later, F. Hoffmann returned to the subject in his *Observationum physico-chymicarum* (Venetiis, 1740), and added that the alkaline earth prepared by treating bitter salt with a fixed alkali, differs essentially from lime, in that when the latter is treated with sulphuric acid, it gives a sparingly soluble salt, which does not taste bitter, and is nearly without taste. Hence bitter salt is composed of sulphuric acid and a kind of alkaline calcareous earth which is different from lime. J. Black, in his paper entitled *Experiments upon magnesia alba, quick-lime, and other alkaline substances* (Edinburgh, 1755), also showed that *magnesia alba* is a compound of fixed air (carbon dioxide) with a peculiar earth which differed from lime in furnishing a soluble sulphate; and he retained for this new earth the name *magnesia*. In Germany the terms *Bittersalzerde*, *Bittererde*, and *Talkerde* were employed. The properties of *magnesia* were described in more detail by A. S. Marggraf⁶ (1759), and by T. Bergman. E. Nauck, L. C. Marquart, and J. J. Nöggerath discuss the occurrence of magnesium metal in old bronzes.

B. G. Sage may have obtained the metal base of *magnesia* in 1777, for he described the following experiment with Epsom or Seidlitz salts:

One ounce of the salt was dissolved in distilled water, and treated with *huile de tartre*—potassium carbonate which had become liquid by deliquescence—the resulting white precipitate was washed, dried, and then mixed with three times its weight of powdered charcoal. The mixture was luted in a glass vessel, and heated for three hours in a reverberatory furnace. The vessel was allowed to cool, and then broken. Mixed with the charcoal were found small, grey, fragile metallic globules which he supposed to be zinc; but he

stated that the quantity obtained was insufficient for proof, but he said that the metal alloyed with copper formed a brass.

In 1808, H. Davy definitely proved that magnesia is the oxide of a metal which he named *magnium*, and added that this word "is undoubtedly objectionable, but magnesium was employed by T. Bergman for metallic manganese, and would consequently have been an equivocal term." The term magnesium was soon afterwards reserved for the metal in magnesia alba, and manganese for that in pyrolusite. For a time some chemists called magnesium, *talcium*. J. B. Trommsdorff discussed the metal derived from Talkerde in 1828.

§ 2. The Occurrence of Magnesium

Magnesium metal does not occur free in nature. This element is considered to be abundantly distributed on the earth's crust. According to F. W. Clarke's estimate,¹ it occupies 8th place in the list of elements arranged in the order of decreasing abundance in the earth's lithosphere, and there is 2.24 per cent. of that element present. The distribution of magnesia in the lithosphere is:

	Igneous (95%)	Shale (4%)	Sandstone (0.75%)	Limestone (0.25%)	Average
MgO . . .	3.74	2.44	1.16	7.89	3.74

N. Ljubavin has also made an estimate of the relative distribution of magnesium on the earth's crust. F. Cornu, and C. A. Young have reported the lines of magnesium in the solar spectrum. G. Rayet, C. Fievez, W. N. Hartley, and A. Secchi found the lines of magnesium in the spectra of the solar protuberances; also in the spectrum of Hercules.

Magnesium occurs as the oxide, *periclase*, MgO ; and as the hydroxides *brucite*, $\text{Mg}(\text{OH})_2$; *hydrotalcite* or *völkerite*, $3\text{Mg}(\text{OH})_2 \cdot \text{Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}$; and *pyroaurite*, $3\text{Mg}(\text{OH})_2 \cdot \text{Fe}(\text{OH})_3 \cdot 3\text{H}_2\text{O}$. There is also the aluminate: *spinel*, $\text{Mg}(\text{AlO}_2)_2$; *magnesioferrite*, $\text{Mg}(\text{FeO}_2)_2$; as well as the aluminoferrites: *pleonaste* or *iron spinel*, $(\text{Mg}, \text{Fe})\{(\text{Al}, \text{Fe})\text{O}_2\}_2$; *picotite* or *chromospinel*, $(\text{Mg}, \text{Fe})\{(\text{Al}, \text{Fe}, \text{Cr})\text{O}_2\}_2$; and *manganospinel*, $(\text{Mg}, \text{Mn})\{(\text{Fe}, \text{Mn})\text{O}_2\}_2$. Magnesium is widely distributed among the silicate minerals (*q.v.*), the commonest of which are *talc*, *chlorite*, and *serpentine*. It is represented by amphiboles, pyroxenes, micas, and olivine in the igneous rocks. There are enormous deposits of the carbonate: *magnesite*, MgCO_3 ; and *dolomite* or *bitter spar*, $(\text{Mg}, \text{Ca})\text{CO}_3$. In addition there are: *brown spar* or *ankerite*, $(\text{Ca}, \text{Mg}, \text{Fe}, \text{Mn})\text{CO}_3$; *breunerite*, $(\text{Mg}, \text{Fe})\text{CO}_3$; and *nesquehonite*, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$;

and the basic carbonates: *hydromagnesite*, $\text{Mg}_2(\text{OH})_2(\text{CO}_3) \cdot 3\text{H}_2\text{O}$; and *lansfordite*, $\text{Mg}_2(\text{OH})_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$. The haloid salts are represented by *sellaite*, MgF_2 ; *bischofite*, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; *carnallite*, $\text{MgCl}_2 \cdot \text{KCl} \cdot 6\text{H}_2\text{O}$; *nocerite*, $(\text{Mg}, \text{Ca})_2\text{OF}_4$; *ralstonite*, $(\text{Na}_2, \text{Mg})\text{F}_2 \cdot 3\text{Al}(\text{F}, \text{OH})_2 \cdot 2\text{H}_2\text{O}$; and *tachhydrite*, $2\text{MgCl}_2 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$. Some mineral springs in Java contain magnesium iodide, MgI_2 , eq. to 0.012 grm. per litre. The sulphates are represented by; *astrakanite*, *blödite* or *simonyite*, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$; *botryogen*, $(\text{FeOH})_4(\text{Mg}, \text{Fe}, \text{Mn}, \text{Ca})_5(\text{SO}_4)_9 \cdot 36\text{H}_2\text{O}$; *cupromagnesite*, $(\text{Cu}, \text{Mg})\text{SO}_4 \cdot 7\text{H}_2\text{O}$; *dumreicherite*, $\text{Mg}_4\text{Al}_2(\text{SO}_4)_7 \cdot 36\text{H}_2\text{O}$; *epsom salts* or *epsomite*, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$; *fauserite*, $(\text{Mg}, \text{Mn})\text{SO}_4 \cdot 7\text{H}_2\text{O}$; *kainite*, $\text{MgSO}_4 \cdot \text{KCl} \cdot 3\text{H}_2\text{O}$; *kieserite*, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$; *klinophailite*, $(\text{Fe}, \text{Al})_2(\text{Fe}, \text{Mg}, \text{Ni}, \text{Ca})$; $(\text{K}, \text{Na})_2(\text{OH})_6(\text{SO}_4)_5 \cdot 5\text{H}_2\text{O}$; *krugite*, $\text{K}_2\text{Ca}_4\text{Mg}(\text{SO}_4)_6 \cdot 2\text{H}_2\text{O}$; *lowite*, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; *magnesia alum*, or *pickeringite*, $\text{MgAl}_2(\text{SO}_4)_4 \cdot 22\text{H}_2\text{O}$; *melanterite*, $(\text{Mg}, \text{Fe})\text{SO}_4 \cdot 7\text{H}_2\text{O}$; *picromerite*, or *schönite*, $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$; *plagiocitrite*, $(\text{Al}, \text{Fe})_3(\text{Fe}, \text{Mg}, \text{Ni}, \text{Ca})(\text{K}, \text{Na})(\text{OH})_6(\text{SO}_4)_5 \cdot 5\text{H}_2\text{O}$; *polyhalite*, $\text{K}_2\text{Ca}_2\text{Mg}(\text{SO}_4)_4 \cdot 2\text{H}_2\text{O}$; *sonomaite*, $\text{Mg}_3\text{Al}_2(\text{SO}_4)_6 \cdot 33\text{H}_2\text{O}$; *vollaitite*, $(\text{Fe}, \text{Al})_4(\text{Mg}, \text{Fe}, \text{K}_2, \text{Na}_2)(\text{OH})_2(\text{SO}_4)_{10} \cdot 14\text{H}_2\text{O}$; *wattevillite*, $(\text{Na}, \text{K})_2(\text{Ca}, \text{Mg})(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$. There is the nitrate, *nitromagnesite*, $\text{Mg}(\text{NO}_3)_2$; and a series of phosphates, arsenates, borophosphates, and borates: *Berzelite*, $(\text{Ca}, \text{Mg}, \text{Mn}, \text{Na}_2)_3(\text{AsO}_4)_2$; *bobierrite*, $\text{Mg}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$; *boracite*, $\text{Mg}_7\text{Cl}_2\text{B}_{10}\text{O}_{30}$; *boromagnesite*, $4\text{Mg}(\text{BO}_2)\text{OH} \cdot \text{Mg}(\text{OH})_2$; *cabrerite*, $(\text{Ni}, \text{Mg}, \text{Co})_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$; *hannayite*, $\text{Mg}_3(\text{NH}_4)_2\text{H}_4(\text{PO}_4)_4 \cdot 8\text{H}_2\text{O}$; *hörnseite*, $\text{Mg}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$; *hydroboracite*, $\text{MgCaB}_5\text{O}_{11} \cdot 6\text{H}_2\text{O}$; *karyinite*, or *caryinite*, $(\text{Mn}, \text{Ca}, \text{Pb}, \text{Mg})_3(\text{AsO}_4)_2$; *lazulite*, $(\text{AlOH})_2(\text{Mg}, \text{Fe}, \text{Ca})(\text{PO}_4)_2$; *lüneburgite*, $2\text{MgHPO}_4 \cdot \text{Mg}(\text{BO}_2)_2 \cdot 7\text{H}_2\text{O}$; *martinite*, $\text{Ca}_2\text{H}_2(\text{PO}_4)_4 \cdot \frac{1}{2}\text{H}_2\text{O}$; *newberyite*, $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$; *picroparmacolite*, $(\text{Ca}, \text{Mg})_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$; *pinnoite*, $\text{Mg}(\text{BO}_2)_2 \cdot 3\text{H}_2\text{O}$; *roselite*, $(\text{Ca}, \text{Mg}, \text{Co})_3(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$; *rösslerite*, $\text{MgHAsO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$; *struvite*, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 4\text{H}_2\text{O}$; *sussexite*, $(\text{Mg}, \text{Zn}, \text{Mn})(\text{OH})\text{BO}_3$; *wagnerite*, $\text{Mg}(\text{MgF})\text{PO}_4$; *wapplerite*, $(\text{Ca}, \text{Mg})\text{HPO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$. There is also a number of silicates (*q.v.*).

The waters of numerous springs as a rule contain small quantities of magnesium compounds which appear in the analyses as magnesium sulphate, chloride, or hydrocarbonate; sea-water also contains magnesium which appears in F. W. Clarke's average analysis of oceanic salts as magnesium chloride, 10.88; magnesium sulphate, 4.74; magnesium bromide, 0.22; together with sodium chloride, 77.76; calcium sulphate, 3.60; calcium carbonate, 0.34; and potassium sulphate, 2.46 per cent. The waters of the Dead Sea contain more magnesium chloride than sodium chloride. F. W. Clarke estimates that on the average 0.14 per cent. of magnesium is contained in the waters of the earth.

According to R. Willstätter,² magnesium is an integral part of chlorophyll; and J. Kacher considered it to be an indispensable constituent of plants, saccharomyces, etc.; the ashes of plants usually contain more calcium than magnesium, although the reverse is true for seeds. It is not known how the magnesium is distributed in the organs of plants, but it occurs in the cambium sap of pines as oxalate. R. Kayser found that the amount of magnesium in wine is proportional to the phosphoric acid, and that the smallest amount—0.001 per cent. MgO —was found in Pfälzer wine, and the greatest amount—0.040 per cent. MgO —in Malaga wine. Magnesium compounds also accompany the calcium compounds in animal bodies; and magnesium salts occur in the skeleton, blood, and milk of animals. F. W. Clarke and W. C. Wheeler found it very exceptional for the inorganic parts of sea organisms to be non-magnesian. They found the following percentage amounts in the inorganic matter: Foraminifera, 3.67–11.22; calcareous sponges, 5.37–8.00; madreporian corals, 0.09–0.77; alcyonarians, 6.03–15.73; hydroids, 0.22–1.28; annelids, 0.00–9.72; echinoderms, 5.99–14.08; brachiopods, 0.49–8.63; bryozoans, 0.63–11.08; molluscs, 0.00–2.58; barnacles, 0.79–2.49; and other crustaceans, 4.84–15.99.

A comparison of rock and other analyses makes it probable that the solid crust of the earth contains more calcium than magnesium. Analyses of meteorites reveal more magnesium than calcium; the same remark applies to sea-water, most mineral waters, and lakes in Central and North-Western Asia. Calcium prevails in river waters, in most plants and in animals; some cereals contain more magnesium.

§ 3. The Preparation of Magnesium

Magnesium is usually obtained by the action of sodium on the anhydrous chloride, or by the electrolysis of fused alkali-magnesium chloride. The magnesium chloride was formerly obtained from Stassfurt, but during the 1914-18 war, it was recovered as a by-product at various salt works. It is used as a powder and ribbon for flash-lighting; as a deoxidizer of other metals and alloys; and in making certain alloys—principally Mg-Al alloys. Magnesium occurs in commerce as powder, ribbon, and as ingots or rods. The ribbon is made by pressing the metal in the semi-fluid state into wire; and afterwards flattening it into ribbon by rolling.

The reduction of magnesium oxide.—H. Davy passed the vapour of potassium over red-hot magnesium oxide, and removed the magnesium produced by mercury. J. Walter¹ tried to reduce magnesium oxide by carbon under the conditions which obtain in the manufacture of zinc. The experiments were conducted at low redness and at a white heat, and precautions were taken to isolate the metal, if formed, whether distilled or volatilized. His results were negative, although he considered it would be possible to prepare a kind of *magnesium brass*, i.e. a Mg-Zn alloy, by substituting some dolomite for the zinc ore ordinarily used in the manufacture of zinc. E. von Püttner, however, claimed to have made magnesium by heating burnt magnesite, dolomite, or other magnesian mineral mixed with coal and ferric oxide, and by exposing to a strong white heat in a muffle furnace as in the process for zinc extraction. The vapour of magnesium was condensed in suitable receivers. E. D. Clarke said that when magnesia is mixed with oil, and exposed to the oxy-hydrogen flame, a slag is obtained which crumbles to white pulverulent magnesia when exposed to the air. It will be observed that the possible products of the deoxidation in the reduction of magnesia by carbon: $n\text{MgO} + (n - \frac{1}{2}m)\text{C} = n\text{Mg} + (n - m)\text{CO} + \frac{1}{2}m\text{CO}_2$, are both reduced by the magnesium at a high temp. H. Moissan claimed that "magnesia can be fused, and kept liquid in a carbon crucible without being reduced." P. Lebeau considers that a reaction occurs only between the vapours of carbon and magnesia at the high temp. of the electric arc. R. E. Slade found that the metal can be isolated from a mixture of carbon and magnesia provided the reoxidation of the magnesium by the carbon monoxide is prevented by rapidly removing this gas, say, by working in vacuo, or by absorbing the magnesium by another metal, or by a rapid stream of hydrogen. The condensed magnesium is always associated with a little carbide which gives off acetylene when treated with a dil. acid or water. O. P. Watts also volatilized carbon from a bed of magnesia, and obtained sublimates consisting of mixtures of carbon and magnesium oxide. O. P. Watts found that at very high temp. magnesia and carbon react: $\text{MgO} + \text{C} \rightleftharpoons \text{CO} + \text{Mg}$, and at a lower temp. the reaction is reversed. O. L. Kowalke and D. S. Grenfell found the reduction of magnesia by carbon begins slowly at 1950°, and becomes violent at 2030°. C. Matignon studied the preparation of magnesium by reducing magnesium oxide, magnesium chloride or oxychloride with calcium carbide. O. Knöfler and H. Ledderboge made rods of magnesia and carbon, and used them as the electrodes of an electric arc. To avoid the action of the products of combustion of carbon on the metal, the arc was developed in vacuo, or in an indifferent gas. J. Malovich mixed the oxide, or a salt of magnesium with sulphur and the sulphate or sulphite of another metal, and heated the mass to a temp. above the m.p. but below the volatilization temp. of the metal or alloy to be obtained.

The reduction of magnesium halides by the alkali metals.—A. A. Bussy first prepared magnesium as a coherent metal in 1829 by decomposing red-hot anhydrous magnesium chloride by potassium vapour, following the process previously employed by F. Wöhler for aluminium. J. von Liebig employed the same process. According to R. Bunsen, magnesium reduced with potassium retains a little of the latter metal very tenaciously, and the resulting metal is more malleable than magnesium free from potassium. H. St. C. Deville and H. Caron improved the process, substituting sodium for potassium. They heated the mixture: magnesium chloride, 7 parts; calcium fluoride, 4·8 parts; and sodium, freed from oil, 2·3 parts to bright redness in a clay crucible—E. Sonstadt used an iron crucible. The magnesium which separated in globules was heated nearly to whiteness in a carbon boat placed in an inclined tube of the same material and through which a stream of dry hydrogen was passed. The magnesium which condensed in the upper portion of the tube was melted into large globules with a flux made of calcium fluoride and sodium and magnesium chlorides. They obtained a yield of 45 grms. of magnesium from 100 grms. of sodium. According to H. St. C. Deville and H. Caron, and E. Sonstadt, the metal prepared by the sodium reduction process contains carbon and silicon as impurities, and, if ammonium chloride is present, some magnesium nitride, Mg_3N_2 , as well. To remove carbon, silicon, and nitrogen, H. St. C. Deville and H. Caron distilled the metal in a current of hydrogen at a high temp. According to J. B. A. Dumas, the metal usually contains two-thirds of its volume of occluded hydrogen and a little carbon monoxide, which are removed by heating it in vacuo at a red heat. E. Sonstadt improved the distillation apparatus. The crude metal was placed in an iron crucible fitted with an iron tube passing through the bottom to within an inch of the lid. The crucible was nearly filled with the crude metal; the lid screwed and luted down; and the air displaced by coal gas or hydrogen. When the crucible was heated, the vapour of magnesium passed into the upright tube and, by a process of *distillation per descensum*, collected as a coherent mass in a box placed below. The metal was then melted and cast into ingots. F. Wöhler applied the sodium reduction process to a fused mixture of sodium and magnesium chlorides; A. Matthiessen, to a mixture of magnesium and potassium chlorides with a little ammonium chloride; H. Schwarz, to tachhydrite; C. Tissier, to sodium magnesium fluoride; and E. Reichardt, to carnallite. The latter used a mixture of equal parts of previously fused carnallite, calcium fluoride, and sodium; and he said that ferruginous mica in the carnallite does no harm, but the presence of kieserite is to be avoided since an explosion may be produced when it is present.

F. Lauterborn heated magnesium ferrocyanide with sodium carbonate so as to produce a double cyanide of magnesium and sodium from which the magnesium was obtained by heating it with zinc. T. Petitjean proposed to reduce magnesium sulphide by iron, or by hydrocarbon vapours at a red heat. M. Basset patented a modification of this process.

The electrolysis of aqueous solutions of magnesium salts.—H. Davy tried to make magnesium by the electrolysis of moistened magnesium hydroxide or sulphate with a mercury cathode and subsequently distilling off the mercury, but the results were bad. A. C. Becquerel electrolyzed a conc. soln. of magnesium chloride in the cathode compartment, and a conc. soln. of sodium chloride in the anode compartment of an electrolytic cell. Octahedral crystals deposited on the cathode. F. W. Gerhard and J. Smith electrolyzed a soln. of 228 parts of magnesium sulphate and 132 parts of ammonium sulphate in 35,000 parts of water between 65° and 100°. For an alloy of magnesium and nickel, a nickel anode was used; for magnesium bronze, a copper anode was used and potassium cyanide and ammonium carbonate were added to the electrolytes. M. Rietz and M. Herold prepared a soln. of magnesium oxide or carbonate in an organic acid, to which was added starch or gum, the soln. boiled with sugar, and neutralized with alkali. This was electrolyzed. If alloys of magnesium are required, a cyanide of the required metal is added to the electrolyte, and an anode of that metal used. G. Nahnsen and J. Pfleger have patented a

special electrolysis cell; and H. Decker, the use of a mercury cathode. The production of magnesium by the electrolysis of aq. soln. has not been successful; nor has the electrolysis of soln. of magnesium salts in non-aq. solvents yet proved of practical utility.

The electrolysis of fused magnesium salts.—In 1852, R. Bunsen² prepared magnesium by the electrolysis of magnesium chloride fused in a porcelain crucible. The carbon of the negative electrode was cut to form pockets in which the metal collected, otherwise, the metal, being lighter than the fused chloride, rose to the surface and burned. There is a difficulty in preparing magnesium chloride, for, when an aq. soln. of the salt is evaporated to dryness and fused, the residue contains magnesium oxide, owing to the hydrolysis of the salt and the escape of hydrogen chloride. A. Matthiessen preferred, as electrolyte, a fused mixture of $3\text{KCl} + 4\text{MgCl}_2$, with a little ammonium chloride. The magnesium in this case is largely present as a complex anion, and hydrolysis does not occur so readily. A great deal of commercial magnesium is obtained by the electrolysis of fused carnallite. F. Fischer first recommended the use of an electrolyte of fused carnallite, and showed that the combustion of the magnesium can be prevented by passing a current of a reducing gas over the electrolyte. In R. Grätzel's apparatus, Fig. 1, the iron vessel *A* contains the fused electrolyte, heated externally, and sealed by a lid through which pass the tubes *TT'*, which allow a stream of a reducing or inert gas to be passed over the molten electrolyte, thus protecting the magnesium from oxidation. The vessel *B* has openings *CC* to allow the circulation of the molten electrolyte, and is fitted with a carbon anode, from which chlorine is liberated during the electrolysis. W. Borchers, F. Hornung and F. W. Kase-meyer, E. Haag, etc., have investigated this mode of preparation. According to R. Bunsen, the metal prepared by electrolysis usually contains a very small proportion of aluminium and silicon.

FIG. 1.—R. Grätzel's Electrolytic Cell for Magnesium (Diagrammatic).

Magnesium melts at about 633° ; magnesium chloride at about 708° ; and carnallite at a lower temp. S. A. Tucker and F. L. Jouard attempted to work at 500° , when the metal is produced in a spongy form which is subsequently melted under a flux of calcium chloride and electrolyzed. According to A. Oettel, the best working temp. is about 650° , for then the efficiency of the process is greatest; but by working at that temp. it is difficult to keep the temp. sufficiently constant to prevent the solidification of the magnesium, and therefore A. Oettel recommended 700° – 750° ; and W. Borchers, 700° . A. Oettel worked at 4–8 volts, W. Borchers at 5–8 volts—depending on the current density and temp. The decomposition voltage of magnesium chloride is estimated to be less than 3.2 volts at 700° , and, assuming that this number represents the value for carnallite, the energy efficiency for a current efficiency of 75 per cent. and 6 volts, is $75 \times \frac{1}{6}$ of $3.2 = 40$ per cent.; and a kilogram of metal requires $(1000 \times 2 \times 96540 \times 100 \times 6) \div (24.3 \times 75 \times 3600 \times 1000)$ or 17.7 kilowatt-hrs. A. Oettel showed that the presence of calcium fluoride as a flux favours the coalescence of the globules of magnesium formed at the cathode. If the globules do not coalesce, but pass into the electrolyte, they form a metal fog about the anode, when they are reoxidized. If the carnallite is contaminated with ferric chloride, losses occur owing to the continuous reduction of this salt at the cathode and its reoxidation at the anode. If too high a voltage is used, or if the magnesium chloride content of the bath becomes too low, the magnesium may contain some potassium, and it is then liable to catch fire during the electrolysis. E. Hohler studied the electrolysis of a molten mixture of equi-molar proportions of magnesium, potassium, and sodium chlorides, along with calcium fluoride and a little alkali to keep the electrolyte sufficiently basic. The best working temp. was 750° – 800° , and a 70 per cent. current efficiency was obtained. The cathodic

current density of 27–30 amps. per sq. dm. was used; W. Borchers used 10 amps. per sq. dm.; and A. Oettel, 30–40 amps. per sq. dm. The subject has been discussed by S. T. Allen, and by K. S. Boynton and co-workers.

According to R. Lorenz and F. Kaufler, some magnesium is produced by the contact electrode process—*vide* Fig. 1 in connection with the preparation of calcium. A. Oettel has shown that the resulting rod of magnesium is somewhat brittle; and, owing to the need for high current densities, the potassium content is liable to rise. M. Sprenger removed the chlorine under reduced press. H. M. A. Berthaut used an electrolyte of magnesium and sodium chlorides; A. Feldmann, a mixture of alkali magnesium chloride mixed with some calcium oxide; F. von Kügelgen and G. O. Seward, magnesium oxide dissolved in fused magnesium fluoride and an alkali fluoride; and the latter also used a bath of fused magnesium and calcium chloride with some calcium fluoride; J. T. Morehead, magnesium fluoride or fluoride and chloride mixed with one, two, or more chlorides of the alkali metals. Magnesium alloys can be made directly by electrolyzing a fused bath of magnesium chloride and fluoride with a carbon anode, and an aluminium cathode. This forms a magnesium-aluminium alloy which can be used as a stock in making alloys of any desired composition—*e.g.* F. von Kügelgen and G. O. Seward's process.

T. Svedberg³ prepared **colloidal magnesium** by connecting a glass condenser of 225 sq. cm. surface with the induction coil and attaching the secondary poles to the electrodes, which are immersed in propyl or isobutyl alcohol contained in a porcelain dish. The magnesium was used in a granular form or as wire clippings. When the current is passed, sparks play between the metal particles, and in the course of a few minutes dark-coloured soln. are obtained. These contain no large particles, and hence need not be filtered. The magnesium sol in absolute ether is olive-green, and very readily coagulated; the coagulum is greenish-black, and very vigorously dissolved by dil. acids with the evolution of hydrogen. D. Zavrieff used a modification of T. Svedberg's process, and obtained a colloidal soln. which could be kept two days without flocculation.

§ 4. The Physical Properties of Magnesium

The magnesium prepared by A. A. B. Bussy¹ was a brilliant silver-white metal, and that by H. St. C. Deville and H. Caron had a bluish or violet tinge. According to A. W. Wright, the metal volatilized in an evacuated tube by means of an electric discharge, produces a metallic film which is silvery-white in reflected light, and greyish-blue by transmitted light. R. Bunsen noted that the metal has a crystalline fracture. S. Kalischer could detect no crystals structure by etching the rolled metal, and he found that although most metals naturally have a crystalline structure, some readily lose this structure by mechanical processes, but assume it again under the influence of heat. According to C. Hlawatsch, and A. des Cloizeaux, the **crystals** prepared by J. B. A. Dumas, by sublimation in a stream of hydrogen, are hexagonal prisms, $a:c=1:1.6242$. These crystals have also been studied by E. Bamberger, and L. Ditscheiner. Regular hexagons were obtained by etching with dil. sulphuric acid, or with chlorine. Z. Jeffries and R. S. Archer give 150° as the lowest temp. at which the recrystallization of the cold-worked metal has been observed. G. T. Beilby showed that the crystalline structure of the metal is hidden when the surface is polished owing to the formation of an amorphous glass-like film which can be removed by an etching liquid. L. Hamburger made an ultra-microscopic examination of these films of the metal. **X-ray spectrograms**, by A. W. Hull, and H. Bohlin, showed a structure in agreement with the holohedral hexagonal crystals. The arrangement of the atoms is that of hexagonal close packing, that is, the arrangement which equal hard spheres assume when closely packed, except that the structure is shortened by about 0.5 per cent. in the direction of the hexagonal axis. The side of the hexagonal lattice is 3.22 Å., height 5.23 Å., and the closest approach of the atoms is 3.22 Å. As in the face-centred cubic lattice, each atom has twelve equidistant near neighbours, but in a slightly different arrangement. G. Jäger made an estimate of the **molecular diameter** of magnesium; W. L. Bragg gave $0.142\mu\mu$ or 1.42 Å. for the radius of the atomic spheres; M. N. Saha, 0.95 Å.; K. F. Slotte estimates the edge of the molecular cube of the liquid and solid to be 7.3×10^{-9} cm. C. T. Heycock and F. H. Neville estimated the **molecular weight** of magnesium in soln. in lead, and tin. K. Honda and S. Konno gave 1.61×10^8 for the coeff. of normal **viscosity** of hammered magnesium at 20° ; and 0.722×10^8 for the metal annealed at 400° . G. P. Seaman studied the torsional oscillations of magnesium wire between -180° and 500° , and found very little change. C. E. Guye and co-workers measured the effect of temp. on the viscosity of magnesium.

L. Playfair and J. P. Joule's value 2.24 (3.9°) for the **specific gravity** of magnesium is too high, and must have been made on an impure sample. R. Bunsen's value is 1.7430 at 5° ; H. Kopp's, 1.70 at 17° ; H. St. C. Deville and H. Caron's value, 1.75; and H. Wurtz's value, 1.77 at 0° . T. M. Lowry and R. G. Parker found the sp. gr. of purified magnesium was raised from 1.7381 to 1.7429 on filing. This is not usual, the filings, like worked metals, usually have the lower sp. gr. When partially annealed at 180° , they expand, but contract if further annealed at 240° . The at. vol. of magnesium does not fit very well in series with the other elements of the magnesium family, and in this respect, this element fits in better with the calcium family. R. Bunsen found the **hardness** of magnesium to be almost equal to that of calcite. C. A. Edwards gave 38.3 for Brinell's hardness. The subject has been discussed by P. Ludwik, and A. Kürth. A. A. B. Bussy said the metal can be hammered into thin sheets; J. von Liebig, and R. Bunsen found that it can be filed,

and bored, and that at ordinary temp. the **ductility** is scarcely as great as that of zinc. H. St. C. Deville and H. Caron stated that while the crude metal is brittle, purified magnesium is very ductile, and while it cannot be drawn into wire, it can be converted into wire by press. through a die. W. Böhm obtained magnesium foil by rolling the metal at a temp. just below its m.p. J. W. Buchanan found the linear **compressibility** to be 1.054×10^{-6} dynes per sq. cm., or 3.2 kgrms. per sq. cm., per atm. press. between 7° and 12°. T. W. Richards and co-workers found the average compressibility, that is, the fractional change of volume caused by one megabar press. between 100 and 500 megabars, to be 2.7×10^{-7} . W. Sutherland gave 390×10^{-6} grms. per sq. cm. or 3900 kgrms. per sq. mm. for **Young's modulus** or the **modulus of elasticity** at 15°, with the extremes 3520 and 4310 kgrms. per sq. mm. W. Voigt's value for the modulus of elasticity of cast magnesium is 4260 kgrms. per sq. mm. P. Ludwik made some observations on the tensile strength of magnesium. C. J. Burton and W. Marshall observed a rise of 0.00047° per atm. increase of press.

According to W. Sutherland, the ratio of the **rigidity** or torsion modulus at 100° to the value at zero is 0.943, and his value for the absolute value in kgrms. per sq. mm. is 1300; H. Tomlinson's, 1720; C. Schäfer's, 1181; W. Voigt's value for the cast metal is 1710, with a change of -30 per cent. per 100° rise of temp. F. Melde found the **velocity of sound** in magnesium to be 4602 metres per second.

E. Grüneisen² found the **coefficient of linear expansion**, α , of magnesium between -190° and 17° to be 0.00002130; and from 17° to 100°, 0.00002610, or 0.0000250 at 18°; and for the expansion from absolute zero to the m.p., $T_s^\circ \text{K}$, he gave 0.0248 or $0.00000277 T_s^{1.337}$, where $T_s = 903^\circ \text{K}$. K. Scheel found the linear expansion of magnesium between 0° and θ° to be

δl	0°	100°	200°	300°	400°	500°
	0	2.60	5.39	8.36	11.53	14.88 mm. per metre

and he represented the results by $\delta l = 0.02507\theta + 0.00000936\theta^2$. J. Desch made some observations on the expansion of magnesium at temp. down to -190°. R. Bunsen said magnesium melts at a red heat, and H. St. C. Deville and H. Caron that it melts near the m.p. of zinc. The reported values for the **melting point** of magnesium range from the 500° of A. Ditte to the 800° of V. Meyer; C. T. Heycock and F. H. Neville gave 632.5°-632.8°; G. Grube, 650.9°; S. F. Schemtschuschny, and R. Vogel, 649°; C. H. Mathewson, G. G. Urasoff, and P. Sahmen, 650°; G. Voss, and N. S. Kurnakoff and N. J. Stephanoff, 651°; N. Beer, 632.6°. According to W. Guertler and M. Pirani, the best representative value is 651°. F. Wöhler noted the volatility of magnesium, and H. St. C. Deville estimated that the **boiling point** is near that of zinc, A. Ditte said about 1100°. H. C. Greenwood gave 1120° for the b.p., while H. von Wartenberg gave a value over 1200°. V. and A. Meyer stated that the metal does not volatilize at a white heat in an atm. of carbon monoxide; while H. Cretier said that volatilization begins below the m.p.; and W. C. Roberts-Austen said that the metal has an appreciable vap. press. at ordinary temp. G. Bartha obtained a partial evaporation of magnesium in vacuo at 580°. H. St. C. Deville and H. Caron purified the metal by distillation, and obtained a black crystalline residue of magnesium nitride. J. B. A. Dumas obtained good crystals by sublimation in vacuo at a red heat. A. Schuller noted that the molten metal attacks glass, and C. Margot found that the adhesion of molten magnesium to glass is due to the formation of a film of oxide on the metal, and that the film can be removed by rubbing. M. Knudsen found that the condensation of the vapour of magnesium on a clean glass or mica surface, has a critical temp., -183° to -78°, below which all the vapour is retained, and above which a fraction is repelled. J. W. Richards estimated the latent **heat of fusion** to be 58 cal.; and the latent **heat of vaporization** 31.580 cal. per mol., or 1315 cal. per kilogram. E. van Aubel, and A. Wehnelt and C. Musceleanu observed 1700 cal. per mol. H. V. Regnault gave 0.2499 for the **specific heat** of magnesium, containing 0.06 per

cent. of silicon and 0.08 per cent. of aluminium and iron. H. Schimpff found over the range -190° to 100° , and N. Stücker, over the range 20° to 650° :

	-190° to 17°	-79° to 17°	17° to 100°	20° to 100°	20° to 350°	20° to 650°
Sp. ht.	0.2046	0.2284	0.2475	0.24922	0.28081	0.32996

E. Grüneisen found 0.2068 between -190° and 17° , and 0.2485 between 17° and 100° ; T. W. Richards and F. G. Jackson gave 0.208 between -188° and -20° , and for the **atomic heat** between -188° and 20° , they gave 5.06, and between 20° and 100° , 6.0. P. Nordmeyer and A. L. Bernoulli, etc., have also made determinations of the sp. ht. of magnesium at different temp. R. J. Brunner gave for magnesium at θ° :

	-273°	-200°	-100°	0°	100°	200°	400°	500°
Sp. ht.	0.1104	0.1622	0.2101	0.2386	0.2557	0.2691	0.3171	0.3673
At. ht.	2.689	3.949	5.116	5.810	6.226	6.554	7.721	8.944

P. Schübel obtained 0.2475 at 100° ; 0.2526 at 197° ; 0.2605 at 304° ; 0.2631 at 400° ; and 0.2680 at 500° . E. D. Eastman and W. H. Rodebush also determined values for C_p and C_v at temp. ranging from 74.9° K. to 288.5° K. W. Nernst and F. Schwes found $C_p=4.558$ at 93.8° K., and 0.335 at 27.2° K. G. N. Lewis and co-workers, and E. D. Eastman found the **atomic entropy** at 25° and one atm. to be 8.3 cal. per degree. L. Lorenz found the **thermal conductivity** in cal. per cm. per sec. per degree difference of temp. to be 0.3760 at 0° , and 0.3760 at 100° . The **heat diffusivity** of magnesium is 0.883 computed from $h^2=k/CD$, where k is the conductivity, C , the sp. ht., and D , the sp. gr.

P. Drude³ estimated the **index of refraction** of magnesium to be 0.37 for $\lambda=0.589\mu$; the corresponding **absorption index** was 4.42; and the percentage **reflecting power**, 93. W. W. Coblentz found the reflecting power of magnesium for light of wave length λ to be:

Wave length, λ	0.5	0.6	0.8	1.0	2.0	4.0	7.0μ
Reflecting power	72	73	74	74	77	84	91 per cent.

Plane polarized light reflected from a polished surface is generally elliptically polarized, and for a certain angle, the **angle of principal incidence**, ϕ , $77^{\circ} 57'$, the change is 90° , and if the plane polarized incident beam has a certain azimuth, **angle of principal azimuth**, ψ , $42^{\circ} 42'$, circular polarized light results. The **refraction equivalent** of magnesium in salts for rays of infinite wave length is 6.51, according to J. Kanonnikoff, and 6.7, according to J. H. Gladstone, when calculated by J. H. Gladstone and T. P. Dale's formula. W. J. Pope gave 8.81 for the eq. refraction of magnesium for the D-ray. S. Procopiu found that the birefringence of toluene is positive, but negative when finely divided magnesium is suspended therein. Similarly with benzene, etc.

R. Bunsen and H. E. Roscoe measured the **actinic value of the magnesium light** compared with that of the sun. The visible brightness of the sun's disc, as measured by the eye, is 524.7 times as great as that of burning magnesium when the sun's zenith distance is $67^{\circ} 22'$, while at the same zenith distance, the sun's chemical brightness is only 36.6 times as great. This emphasizes the value of the magnesium light as a source of chemically active rays. The intensity of the magnesium flame was also studied by L. Troost, J. M. Eder, and H. Vogel. The combustion of 0.1 grm. of the metal can theoretically furnish as much light as 74 stearin candles burning for 10 hrs. A magnesium wire, 0.297 mm. diameter, burning in air gives as much light as 74 stearin candles each weighing 100 grms. K. Heumann found that the magnesium flame in sunlight gives an intense shadow, and he assumed that the flame of magnesium is non-luminous, and that the luminosity of the burning metal is really due to the magnesium oxide suspended in the flame. A. R. von Schrötter also studied the nature of the magnesium light. E. L. Nichols found that the efficiency of the **light-energy** of burning magnesium is 10 per cent. of the heat

of combustion, a value unapproached among the known transformations of energy used in the production of light.

According to T. Tommasina, magnesium becomes **fluorescent** when used as electrode in an inductorium, under water or alcohol, but not under vaseline or petroleum. W. Ramsay and J. F. Spencer⁴ gave the order Al, Mg, Zn, Sn, Cd, Pb, . . . for the **photoelectric effect** with polished metal surfaces and a mercury vapour lamp with uviole glass; K. Herrmann gave Al, Zn, Mg, Sn, Bi, Cd, Pb, . . . with a carbon arc-lamp; R. A. Millikan and G. Winchester gave Al, Mg, Sb, Zn, Pb, . . .; the latter also gave 0.839 volt at 26° for the positive potential of magnesium in vacuo in ultra-violet light. T. C. Sutton, and A. E. Henning and W. H. Kadesch have also studied the phenomenon with magnesium. A. Nodon found a sheet of magnesium is opaque to the penetrating solar photogenic radiations, but a metal of high valency is not. The absorption coefficient, μ , for the β -rays is approximately proportional to the sp. gr. D , and for magnesium $\mu/D=5.1$. W. Duane, and E. Hjalmar measured the absorption frequencies for the X-rays.

W. A. Miller⁵ first examined the spectrum of magnesium as obtained by introducing the chloride in the alcohol flame. The **spectrum** of burning magnesium has three green lines—5184, 5173, and 5167—and is very rich in the chemically active rays at the violet end of the spectrum. The light causes the detonation of a mixture of hydrogen and chlorine; it colours silver chloride dark blue in a few seconds, and, according to A. Schrötter, and H. Lallemand, it causes numerous bodies to phosphoresce. Magnesium salts do not impart any colour to the flame. The spark spectrum of the chloride shows an intense line, 5184; and a strong double line, 5173–5167, at 76 on the scale of Fig. 2. The double line is really a triplet, and

FIG. 2.—Spark Spectrum of Magnesium Chloride.

it coincides with the dark "little b " line of the solar spectrum. There is a shaded band beginning at 83.8, and fading away towards the blue end of the spectrum; and a feeble line at 4705, and another indigo line at 4481. The blue band in the spectrum is supposed to be due to magnesium oxide, and it is very bright in the spectrum of burning magnesium; the other lines are due to the metal itself. C. Cappel claims that 2×10^{-6} mgrms. of magnesium can be detected by the spark spectra; and W. N. Hartley found 10^{-7} mgrms. by photographing the ultra-violet spark spectrum. G. Kirchhoff identified the three green lines in the spectrum of magnesium with the "little b " lines in the solar spectrum. E. Carter examined the vacuum spark spectrum. R. W. Wood and D. V. Guthrie, F. Exner and E. Haschek, G. D. Liveing and J. Dewar, J. C. McLennan and co-workers, A. Cornu, and W. A. Miller examined the **ultra-violet spectrum**. J. Meunier found in the ultra-violet region the band composed of the rays $\lambda=3810, 3829, 3833, 3838, 3851, 3858, 3861$, and another band consisting of the rays $\lambda=3885, 3912, 3940, 3960, 3980$. Nine other rays between $\lambda=3700$ and 3780 have been noticed and their wave lengths approximately determined. Of the salts of magnesium, the chloride, oxychloride, sulphate, nitrate, oxide, and carbonate gave the above spectrum. The pyrophosphate is not, apparently, reduced under these conditions and does not give the above spectrum, since incandescence phenomena, corresponding with the continuous spectrum, are produced. F. Paschen, H. Lehmann, and H. Becquerel examined the **ultra-violet spectrum** of magnesium; W. W. Coblentz, R. A. Millikan and H. Becquerel, the **infra-red spectrum**; J. Stark and G. von Wundt, the effect of the **canal rays**; F. L. Mohler and P. D. Foote studied the **X-ray spectrum** of magnesium; W. Miller and T. Royds investigated the **Zeeman effect**. T. Takamine and N. Kokubu studied the effect of an *electric field* on the spectrum of magnesium. C. Olmsted studied the spectra of *magnesium fluoride, chloride, bromide, and iodide*; W. N. Hartley,

and E. E. Brooks, the spectrum of *magnesium nitride*; W. N. Hartley, *magnesium sulphate*; G. D. Liveing and J. Dewar, G. L. Ciamician, J. N. Lockyer, W. N. Hartley and H. Ramage, E. E. Brooks, A. Fowler and H. Payn, R. A. Porter, and O. H. Basquin, *magnesium hydride*; E. E. Brooks, W. N. Hartley and H. Ramage, J. M. Eder, E. Demarçay, L. de Boisbaudran, A. Gouy, W. M. Watts, H. Crew and O. H. Basquin, C. Olmsted, etc., the spectrum of *magnesium oxide*. G. A. Hemsalech showed that the spectral lines excited thermo-electrically and chemically are of the same type. E. Gehrcke and L. C. Glaser examined the *band spectrum* of magnesium. A. de Gramont and G. A. Hemsalech studied the effect of electric charge on the spectral lines of magnesium.

The spectra of magnesium, zinc, and cadmium are characterized by the presence of triplets repeated over and over again; the triplets are close in magnesium, wider in zinc, and still wider in cadmium. H. Kayser and C. Runge arrange the triplets of magnesium in two series which they believe to be subordinate series, and represent the oscillation frequencies by the formulæ:

FIRST SERIES.

$$10^8\lambda^{-1} = 39796 \cdot 10 - 130398n^{-2} - 1432090n^{-4}$$

$$10^8\lambda^{-1} = 39836 \cdot 79 - 130398n^{-2} - 1432090n^{-4}$$

$$10^8\lambda^{-1} = 39857 \cdot 00 - 130398n^{-2} - 1432090n^{-4}$$

SECOND SERIES.

$$10^8\lambda^{-1} = 39836 \cdot 74 - 125471n^{-2} - 518781n^{-4}$$

$$10^8\lambda^{-1} = 39877 \cdot 95 - 125471n^{-2} - 518781n^{-4}$$

$$10^8\lambda^{-1} = 39897 \cdot 91 - 125471n^{-2} - 518781n^{-4}$$

which agree with 39 lines in the arc-spectrum of magnesium, with very small differences: except in the red, when the difference between the observed and calculated

λ	6000					5000					4000					3500					3000					2500				
$\frac{1}{\lambda}$	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38	39	40	41	42

FIG. 3.—Series in Spectra of Magnesium, Zinc, Cadmium, and Mercury.

values is about one per cent. The coeff. of n^{-2} and n^{-4} in each series are the same, meaning that the spacing of the lines in the successive triplets are the same within the limits of experimental error. The arrangement of the lines in the series in the spectra of magnesium, zinc, cadmium, and mercury is shown in Fig. 3, the numbers of the lines represent the values assigned to n in the above formulæ. This subject has been discussed by A. Fowler. J. C. McLennan found that the vapour of magnesium gives a single line spectrum $\lambda = 2852 \cdot 22$, when the heated vapours are bombarded by electrons whose energy is acquired by an arcing potential of 8.2 volts with Wehnelt's cathode and positive terminal. The **ionization potential** of magnesium vapour calculated by J. C. McLennan is 4.28 volts; M. N. Saha gave 7.65 volts or 1.76×10^5 cal.; F. L. Mohler and co-workers, 8.0 volts; and J. C. McLennan and J. F. T. Young, 7.65 volts; K. T. Compton gave 3.63–4.28 for the minimum ionization potential. F. L. Mohler and co-workers gave 2.65–4.42 volts for the **resonance potential**. E. Rutherford and J. Chadwick obtained little, if any, evidence of the emission of long-range particles detached by scintillations on a zinc sulphide screen when α -particles pass through magnesium; and H. R. von Traubenberg found the range of the α -particles in magnesium to be 57.8×10^{-4} cms. M. N. Saha estimated the **temperature of complete ionization** to be 24,000° K., **luminescence** of the vapour to begin at 7500° K., and the temp. of maximum luminescence to be 11,000° K. B. E. Moore studied the excitation stages in the arc spectrum of magnesium.

According to A. Matthiessen,⁶ the **electrical conductivity** of magnesium is a little less than that of zinc. L. Lorenz gave 24.47×10^{-5} for the electrical conductivity at 0° , and 17.5×10^{-5} at 100° ; J. R. Benoit gave 24×10^{-4} for the cold hammered metal at 0° ; and H. Ihle, 20.8×10^{-4} at 19° . J. Dewar and J. A. Fleming, and H. Dickson gave for zinc-free magnesium at -183° , 99.9×10^{-4} mhos; at -78° , 33.7×10^{-4} ; at 0° , 23×10^{-4} ; at 98.5° , 16.7×10^{-4} ; and at 142.2° , 13.5×10^{-4} ; in addition, G. Niccolai gave :

	-189°	-100°	0°	100°	400°
Conductivity .	78.4×10^{-4}	37.8×10^{-4}	23.2×10^{-4}	16.9×10^{-4}	8.41×10^{-4}

E. F. Northrup measured the electrical resistance of magnesium between 20° and 100° . L. Cailletet and E. Bouty, and P. W. Bridgman gave 0.00390 for the *temperature coefficient* of the electrical conductivity between -88.31° and 0° . J. Dewar and J. A. Fleming gave 0.00381 between 0° and 100° . P. W. Bridgman found -0.0555 for the *pressure coefficient* of magnesium at 0° ; and later, with a purer sample, he obtained 0.05390 between 0 and 12,000 kgrms. per sq. cm. press. The results are :

		0°	50°	100°
Electrical resistance .	.	1.0000	1.1975	1.3900
Press. coeff. {	0 kgrm. .	-0.05477	-0.05462	-0.05473
	12×10^3 kgrms. .	-0.05311	-0.05348	-0.05341
	Average .	-0.054080	-0.054065	-0.054018

It was further found that the purer the sample, the smaller the temp. coeff. This is not usual, although L. Holborn found it to be the case with aluminium. W. P. Davey gave 0.90 A. for the **ionic radius** of the magnesium ion in magnesium oxide.

Magnesium is electrically negative against the metals of the alkalis and alkaline earths. According to J. F. Daniell and F. Exner, the **electromotive force** of an element $\text{Mg}|\text{Br}$ is 2.36 volts, and of an element $\text{Mg}|\text{I}$, 1.57 volts. W. R. Mott measured the potential difference between magnesium and some of its salt soln., at 20° against a normal electrode -0.5 volt, and found with $\text{Mg}-\text{NaCl}$ (2 mols per litre), +1.163 volts; $\text{Mg}-\text{NaOH}$ (one mol per litre), +1.111 volts; $\text{Mg}-\text{KOH}$ (one mol per litre), +1.140 volts; $\text{Mg}-\text{KOH}$ (0.1 mol per litre), +1.105 volts; and $\text{Mg}-\text{MgSO}_4$ (one mol per litre), +1.366 volt. According to C. M. van Deventer, magnesium, when immersed in a mixture of alcohol and water, may become cathodic to zinc, immersed in dil. sulphuric acid. The change of potential is due to the formation of a layer of insoluble badly conducting salt on the magnesium. N. R. Dhar studied the e.m.f. of magnesium against aq. soln. of magnesium and potassium chlorides, and gave 0.81 volt for the potential against water. The e.m.f. in water or a neutral electrolyte is less than in a soln. of its own salt. W. Kistiakowsky measured the potential of cells of the type $\text{Mg}|N\text{-Mg-ions}|N\text{-H-ions}|\text{H}_2$ on Pt. The maximum potential of the **magnesium electrode** agrees with the assumption that the heat evolved by the reaction is $\frac{1}{2}\text{Mg} + \text{H}_2\text{O} = \frac{1}{2}\text{Mg}(\text{OH})_2 + \frac{1}{2}\text{H}_2 + 40.28$ Cals.; and it is inferred that the potential of the magnesium electrode is fixed by the free energy of the reaction $\frac{1}{2}\text{Mg} + \text{OH}' - \ominus = \frac{1}{2}\text{Mg}(\text{OH})_2$, just as the potential of the hydrogen electrode is fixed by the free energy of the reaction $\text{H}_2\text{O} + \ominus = \frac{1}{2}\text{H}_2 + \text{OH}'$. The fact that the potential of the magnesium electrode is independent of the conc. of the Mg-ions , and that it reaches a maximum in reducing soln., and a minimum in oxidizing soln., is taken to support the hypothesis. J. Heyrovsky found the decomposition potential of magnesium to be -1.903 volts. L. Cambi found evidence of the **passivity of magnesium** and its amalgams during his measurements of the e.m.f. of this metal in pyridine soln. of magnesium chloride or iodide, but not when methyl alcohol was used as solvent.

The electric current generated by heating a junction of two different metals, or the same metal in two different conditions, is called a thermoelectric current, or the **Seebeck effect**. If the two junctions of a couple be initially at T° , and the temp. of one be raised by a small increment dT , when dE is the corresponding e.m.f., the ratio dE/dT is the thermoelectric power

of the two metals at T° . When an electric current flow passes in a closed circuit containing different metals, heat is absorbed at the junction which would have to be heated in order to give a thermoelectric current in the same direction as that given by the battery, and conversely for the other junction. The phenomenon is called the **Peltier effect**. Again, if a current passes in a closed circuit containing different metals with hot and cold junctions, there is an absorption or evolution of heat. Thus, heat is absorbed when a current flows from the cold to the hot junction in copper, and conversely; heat is evolved when a current flows from cold to hot in iron, and conversely. This phenomenon is called the **Thomson effect**. The Thomson effect with copper, silver, zinc, cadmium, and antimony is said to be positive; with iron, bismuth, cobalt, nickel, and platinum it is said to be negative; and with lead, the effect is neutral.

J. Dewar and J. A. Fleming's value for the **thermoelectric force**, or the **Seebeck effect**, of magnesium at 100° is 0.42 millivolt; K. Noll's 0.40 millivolt; and E. Wagner's, 0.43 millivolt; and the current goes to the platinum from the junction, at 0° . P. G. Tait represents the thermoelectric powers, E , of a circuit of magnesium and lead with one degree difference of temp. as $dE/d\theta = 2.22 - 0.0094\theta$ microvolts, when θ represents the mean temp. of the two junctions; when θ is 20° and 50° , the respective thermoelectric powers are 2.03 and 1.75 microvolts; the neutral point is 236° , when $dE/d\theta$ is zero. P. W. Bridgman found the thermal effect, E , of magnesium against lead at atm. press. to be very small, $E = (-0.095\theta + 0.00004\theta^2) \times 10^{-6}$ volts; the Peltier effect, P , against lead is $P = (-0.095 + 0.00008\theta)(\theta + 273) \times 10^{-6}$ volts; and the Thomson effect, σ , against lead is $\sigma = 0.00008(\theta + 273) \times 10^{-6}$ volts per degree. The thermal e.m.f. of a couple composed of one branch of the uncompressed metal and the other compressed at p kgrms. per sq. cm., with the junctions at 0° , are in volts $\times 10^6$,

p		10°	20°	40°	60°	80°	100°
2,000	.	-0.17	-0.33	-0.67	-1.00	-1.34	-1.67
6,000	.	-0.57	-1.04	-2.18	-3.43	-4.57	-5.71
12,000	.	-1.30	-2.59	-5.18	-7.78	-10.37	-12.96

The curves of e.m.f. at constant temp. against press. are concave upwards corresponding with an increasing proportional effect at higher press.; at constant press., the e.m.f. against temp. is linear. For the **Peltier effect** between the compressed and uncompressed metals, in joules per coulomb $\times 10^6$, P. W. Bridgman found:

		0°	20°	40°	60°	80°	100°
p	2,000	-4.56	-4.91	-5.24	-5.56	-5.89	-6.23
	6,000	-15.6	-16.7	-17.9	-19.0	-20.1	-21.1
	12,000	-35.4	-38.0	-40.6	-43.2	-45.8	-48.4

The Peltier effect is thus negative and increases numerically with both temp. and press. The **Thomson effect** was found to be everywhere zero. According to M. E. Verdet, magnesium and its salts are diamagnetic; S. Meyer gave $+0.57 \times 10^{-6}$ for the **magnetic susceptibility** of crystalline magnesium at 20° ; and K. Honda gave $+0.55 \times 10^{-6}$ at 18° . P. Pascal found the at. coeff. of magnetization to be -113×10^{-7} units. A. Günther-Schulze⁷ studied the **electrolytic valve action** of magnesium in aq. salt soln.

§ 5. The Chemical Properties of Magnesium

Magnesium is used for making illuminating powders for flash-light photography; and for star-shells for illumination in warfare; it is used as a deoxidizer in making bronzes, nickel-silver, and other alloys; it is used in conjunction with aluminium for making light alloys—e.g. magnalium; and it is used in dehydrating oils—e.g. aniline oil—etc. The compounds of magnesium are used medicinally; in making

cements; and magnesia is employed for making the so-called magnesite bricks for lining basic steel furnaces, and electric steel furnaces.

According to J. B. A. Dumas,¹ magnesium absorbs about two-thirds of its vol. of **hydrogen**, which is evolved in vacuo at a red heat. C. Winkler stated that hydrogen is not absorbed by hot magnesium, but a slow absorption does occur if the metal be mixed with magnesia, and heated to redness in a stream of hydrogen for 4 hrs., and he believed that 6.42 per cent. of the metal has been converted into **magnesium hydride**. No other chemical evidence of the existence of magnesium hydride has been adduced. According to A. Fowler, the dark grey deposit formed by the passage of the arc in hydrogen probably contains magnesium oxide, since, when dissolved in acids, it gives less hydrogen than would be furnished by an equal weight of magnesium; there is no chemical evidence of the formation of a hydride. O. H. Basquin noted that the spectrum, in hydrogen, with the rotating metallic arc with aluminium, copper, magnesium, silver, or sodium, has characteristic lines not found with the arc spectrum in air, and "in lieu of a better hypothesis," he assumed that the lines are due to the formation of metal hydrides. W. N. Hartley did not favour the hypothesis because, in the case of sodium, the dissociation at barometric press. is complete at 422°. G. D. Liveing and J. Dewar attributed the line at $\lambda=5210$, and the attendant series to "a mixture of magnesium and hydrogen rather than to a chemical compound, because this expresses the facts, and we have not yet obtained independent evidence of any chemical compound of these elements"; but in a later paper, they stated that "the lines just indicated are due to a combination of hydrogen and magnesium, and are not dependent solely upon the temp." A. Fowler likewise assumed that magnesium hydride is concerned in the production of the flutings in the spectrum of a mixture of hydrogen and magnesium, and that the combination appears to take place directly under the influence of the arc, especially at low press., or with some forms of the spark discharge, or by the combustion of the metal in an atm. containing hydrogen either free or in combination. E. E. Brooks suggested that the compound is in most experiments decomposed as quickly as it is formed, and A. Fowler added that "a perfectly definite conclusion does not at present seem to be possible."

A. A. B. Bussy,² and R. Bunsen found that magnesium does not change in dry **air**, but, in moist air, it is soon covered by a white film of magnesium hydroxide, and H. St. C. Deville and H. Caron found that in ordinary air it is attacked superficially. E. Sonstadt also stated that magnesium contaminated with nitrogen (nitride) is not stable in air. The metal inflames when heated just above its m.p. in air, and burns with an intense white dazzling flame, and a white cloud of magnesium oxide is formed. W. Muthmann and K. Kraft give 540° for the ignition temp. of magnesium in oxygen. According to F. J. Rogers, the temp. of the magnesium flame is 1335°. According to A. K. Christomanos, and W. French, when a cold solid is introduced into the magnesium flame, a black spot surrounded by a white halo of magnesium oxide is formed; according to A. K. Christomanos, and G. Baborovsky, the black deposit may be a suboxide; and A. K. Christomanos, J. W. Mallet, and J. Pinnow say that an appreciable quantity of magnesium nitride is formed in the *smothered combustion* of magnesium, i.e. the combustion of the metal in a quantity of air insufficient to burn all the metal. H. Kämmerer observed the formation of appreciable quantities of nitric oxide when magnesium burns in a cylinder filled with air; P. L. Aslanoglou noted the formation of ammonia in the oxidation of magnesium in moist air. According to S. Kappel, if air be passed over magnesium in contact with potassium hydroxide, nitrous acid, ozone, and hydrogen peroxide are formed; if the metal is in contact with aq. ammonia, magnesium nitride and suboxide are formed. In **oxygen**, magnesium burns quantitatively to the oxide. N. B. Pilling and R. E. Bedworth found that magnesium at 500° in oxygen produces a discontinuous film of oxide which offers no impedance to further oxidation. The oxidation is at the rate of about 0.00052 grm. per sq. cm. per hour, a value about one-third as great as that for calcium at the

same temp. O. Ohmann found magnesium-wool burns with explosive violence when ignited with a Bunsen's burner.

According to A. A. B. Bussy, cold, recently boiled **water** is without action on magnesium, while with boiling water, some hydrogen is developed: $\text{Mg} + 2\text{H}_2\text{O} = \text{Mg}(\text{OH})_2 + \text{H}_2$. On the other hand, J. von Liebig stated that boiling water is without action on the metal. R. Bunsen observed that the metal he prepared slowly decomposed cold water. It is not clear if all these samples of metal were free from the alkali metals or the water free from carbon dioxide. D. Vitali found water free from carbon dioxide gives no hydrogen in contact with magnesium. According to C. F. Roberts and L. Brown, magnesium has no action on distilled water which has been freed from gases by boiling and afterwards cooled out of contact with air. It reacts, however, with undistilled water, with unboiled distilled water, or with water which has been boiled and afterwards charged with oxygen or carbon dioxide, varying amounts of hydrogen being liberated. H. T. Barnes and G. W. Scherer showed that some hydrogen peroxide is formed in the reaction. W. Hughes found that the reaction between magnesium and water is very slow at the ordinary temp., but is greatly accelerated in presence of neutral and alkaline salts, such as sodium chloride, sodium hydrocarbonate, sodium carbonate, and magnesium sulphate. Experiments with sodium chloride soln. at 25° have shown that the initial rate at which hydrogen is evolved depends on the concentration of the dissolved salt. The reaction velocity has a maximum value for a soln. containing 32 mols of water per mol of sodium chloride. This maximum cannot be satisfactorily interpreted in terms of the physical properties of sodium chloride soln., and is regarded as evidence in favour of the specific nature of the catalytic action of the electrolyte present. According to A. Ditte, magnesium decomposes water at a temp. exceeding 70° . Water vapour, at not particularly high temp., is decomposed by magnesium; and the phenomenon is used as a lecture experiment—*vide* A. Duboin, H. Leffmann, G. T. Moody, M. Rosenfeld, etc. According to F. Kessler, burning magnesium is not extinguished when plunged into steam.

According to C. Weltzien, and G. Giorgis, a soln. of **hydrogen peroxide** dissolves magnesium; if atm. carbon dioxide be not excluded, the soln. becomes alkaline, and furnishes on evaporation needle-like crystals of magnesium carbonate, soluble in water; while if carbon dioxide be excluded, the metal is dissolved much more slowly, the water becomes alkaline, and on evaporation gives a flocculent residue, not soluble in water. H. T. Barnes and G. W. Scherer showed that with magnesium and aluminium electrodes in contact with water containing dissolved air, the e.m.f. slowly rises to about one volt, although the metals are close together in the electrochemical series; this is due to the formation of hydrogen peroxide by the action of water containing dissolved air on aluminium. When free hydrogen peroxide is added to the aluminium compartment, the e.m.f. rises to about two volts, and then gradually falls as the hydrogen peroxide is decomposed.

H. Moissan³ found that magnesium burns vigorously in **fluorine** *avec beaucoup d'éclat*, forming the fluoride. In 1830, J. von Liebig found moist **chlorine** gas inflames magnesium; and in 1852, R. Bunsen said that the warm metal burns in chlorine, and J. A. Wanklyn and E. T. Chapman said that magnesium remains bright for a long time in cold chlorine. R. Cowper found that dry chlorine gas does not attack magnesium. H. Gautier and G. Charpy kept liquid chlorine for 15 months in contact with magnesium without any appreciable action. R. Bunsen said that warm magnesium does not burn so readily in **bromine** vapour as it does in chlorine; and H. Gautier and G. Charpy, and J. A. Wanklyn and E. T. Chapman found that dry liquid bromine could be kept for a year in contact with magnesium without any appreciable action; bromine water, on the other hand, gives a regular development of hydrogen, and an oxybromide is formed. R. Bunsen said that magnesium burns vigorously when heated in **iodine** vapour, and T. L. Phipson distilled iodine from magnesium without appreciable action. F. J. Faktor stated that a soln. of iodine colours magnesium green, and a film of the iodide is formed,

and J. A. Wanklyn and E. T. Chapman, that an ethereal or alcoholic soln. of iodine acts very slowly on magnesium when warmed. R. Bunsen noted in 1852 that magnesium is readily attacked by **hydrochloric acid**—*vide* action of acids on copper, and also on zinc. P. T. Austen noted that when burning magnesium is introduced into gaseous **hydrogen iodide**, it continues burning for a moment, and is then extinguished. A soln. of bleaching powder, sp. gr. 1.04, was shown by A. D. White to act slowly on magnesium with the evolution of hydrogen; with hypochlorous acid, hydrogen is rapidly evolved and magnesium hypochlorite is formed. According to W. S. Hendrixson, when magnesium reacts with **chloric acid**, about 95 per cent. is converted into chlorate, and the remainder is spent in the reduction of the acid. C. Kippenberger reduced soln. of the chlorates to chlorides by means of magnesium. According to A. Ditte, with a cold aq. soln. of **iodic acid** iodine is liberated, and hydrogen evolved; and a very dil. soln. of the acid is coloured yellow by the iodine. According to D. Vitali, a soln. of iodic acid is first coloured yellow by magnesium, and a brown precipitate is formed containing magnesium iodate, while the colourless soln. contains iodide and iodate.

According to K. Seubert and A. Schmidt, the **alkali chlorides** are reduced to the metals when heated with magnesium in an atm. of hydrogen, lithium chloride being reduced most readily; the **alkaline earth chlorides** are also reduced in a similar way, and the reduction is more readily effected the smaller the at. wt. of the metal. Most **metal chlorides**—*e.g.* the chlorides of copper, silver, gold, zinc, cadmium, mercury, aluminium, thallium, lead, tin, arsenic, antimony, bismuth, chromium, tungsten, molybdenum, uranium, manganese, iron, cobalt, nickel, and platinum—are also reduced when heated with magnesium. According to S. Möller, *chemiluminescence* occurs when an **alkyl halide** in ethereal soln. reacts with powdered magnesium.

According to J. von Liebig,⁴ molten **sulphur** reacts with magnesium, and, according to R. Bunsen and J. Parkinson, the reaction is vigorous with the red-hot metal, and the metal burns vigorously in sulphur vapour, forming magnesium sulphide. A. Orłowsky found that the reaction between magnesium and sulphur or a soln. of sulphur in carbon disulphide is exceedingly slight at ordinary temp. According to T. L. Phipson, and F. G. Reichel, the sulphur can be volatilized by heat from an admixture with magnesium filings without reaction. According to W. Spring, a mixture of sulphur and finely divided magnesium forms a polysulphide when subjected to a press. of 6500 atm. L. Kessler found that burning magnesium continues burning in an atm. of **hydrogen sulphide**, and also in an atm. of **sulphur dioxide**. In the latter case J. Parkinson found that there is a separation of sulphur, and the formation of a residue which gives off red fumes when treated with nitric acid, and magnesium sulphate being formed. According to J. Uhl, the residue after the combustion in sulphur dioxide contains sulphate, sulphite, and sulphide. With sulphurous acid, P. Schweitzer obtained sulphite, thiosulphate, and trithionate; and M. Billy obtained magnesium tetrathionate with a soln. of sulphur dioxide in absolute alcohol. C. Brückner found that when **sulphur trioxide** vapour is passed over red-hot magnesium powder, magnesia, sulphur dioxide, and magnesium sulphide are formed. R. Bunsen stated that magnesium dissolves with difficulty in conc. **sulphuric acid**, and J. von Liebig observed the development of sulphur dioxide, and A. Ditte, hydrogen sulphide and sulphur. The rate of dissolution of magnesium in dil. acids has been investigated by N. Kajander, and he found that the wt. of metal dissolved in unit of time is, *ceteris paribus*, a simple function of the mol. wt. of the acid, of its conc., and of the nature (water, saline soln., etc.) of the medium in which the reaction is effected. Heat accelerates the reaction only because it diminishes the internal friction of the liquid. P. B. Ganguly and B. C. Banerji found that a rod of magnesium partly immersed in dil. acid is most attacked near the surface of the liquid. K. Seubert and A. Schmidt found **sulphur chloride**, S_2Cl_2 , gives sulphur when heated with magnesium.

According to C. Brückner, when an **alkali sulphite** is heated with magnesium, alkali sulphide and sulphate are formed, while the **heavy metal sulphites**, *e.g.* zinc

sulphite, furnish sulphur dioxide, and the metal oxide, sulphide, and sulphate. When the **alkali sulphates** are calcined with magnesium in a stream of nitrogen, the alkali polysulphide, thiosulphate, and sulphur are formed, but no sulphur dioxide is evolved; while the **alkaline earth sulphates**, and the **sulphates of magnesium, zinc, aluminium, and nickel** give sulphur dioxide and oxide; **cupric sulphate** also gives metallic copper; and the **sulphates of manganese and iron** give the higher metal oxide, thiosulphate, and sulphide as well as sulphur dioxide and sulphur. Some sulphates react giving sparks when they are triturated with magnesium. The products of the reaction in the cold are not the same as with heat; thus **nickel sulphate** gives nickel sulphide and magnesium oxide in the cold, and nickel sulphide, sulphur dioxide, and sulphur when heated. According to F. J. Faktor, when magnesium is calcined with **sodium thiosulphate**, the sulphide and sulphate are formed; and when magnesium is heated with a soln. of sodium thiosulphate the reactions are symbolized: $\text{Mg} + 2\text{H}_2\text{O} = \text{Mg}(\text{OH})_2 + \text{H}_2$; $\text{Na}_2\text{S}_2\text{O}_3 + \text{H}_2 = \text{H}_2\text{S} + \text{Na}_2\text{SO}_3$; $\text{Mg}(\text{OH})_2 + 2\text{H}_2\text{S} = \text{Mg}(\text{SH})_2 + 2\text{H}_2\text{O}$. H. Mouraour also studied the action of magnesium on soln. of sodium thiosulphate. According to M. G. Levi, E. Migliorini, and G. Ercolini, magnesium rapidly dissolves in a soln. of **potassium persulphate**, with the evolution of gas; and the turbulent action of an aq. soln. of **ammonium persulphate** on magnesium, furnishes ammonia gas, etc.

F. W. Newmann⁵ studied the absorption of **nitrogen** by magnesium at the cathode of a vacuum tube. Magnesium is not attacked by nitrogen in the cold. H. Erdmann found liquid nitrogen extinguished the flame of burning magnesium. F. Briegleb and A. Geuther prepared magnesium nitride by heating the metal in a stream of nitrogen or **ammonia**. H. N. Warren added that there is very little action below a red heat, although the metal becomes less fusible and burns with violent decrepitations when ignited; at a dull red heat, the metal becomes yellow with a golden lustre; and at a full red heat it forms an orange-yellow powder of the nitride. According to T. L. Phipson, and G. A. Maack, aq. ammonia does not react with magnesium in the cold. Dry liquid ammonia, according to F. G. Cottrell, does act slowly on magnesium, forming a faint blue soln., which gradually decomposes into amide and hydrogen, in a manner analogous with the corresponding reaction between liquid ammonia and the alkali and alkaline earth metals. Liquid **acetylene** at ordinary temp. has no appreciable action on the metal. Electrical conductivity measurements show no signs of the formation of magnesium aminocarbide or aminoacetylide, but mixtures of liquid ammonia and acetylene readily act on magnesium, forming a crystalline compound, $\text{MgC}_2 \cdot \text{C}_2\text{H}_2 \cdot 5\text{NH}_3$, and some ethylene and ethane. The product is stable below 2° , but at this temp. it loses the eq. of 1.5NH_3 , and the residue is stable between 2° and 60° , when it loses ammonia and leaves behind a mixture of magnesium amide and nitride. According to C. A. L. de Bruyn, anhydrous **hydroxylamine** is without action on powdered magnesium. L. Kessler found that the flame of burning magnesium is not extinguished in **nitrous oxide** or in **nitric oxide**; and P. Sabatier and J. B. Senderens found that magnesium filings begin to react with **nitrogen peroxide** at a dull red heat. R. Weber found **nitrogen pentoxide** only exerts a slight action on the metal; and J. J. Sudborough, that **nitrosyl chloride** has no action on the metal either in the cold or at 100° . According to W. N. Hartley, aq. soln. of **nitrates** are reduced by magnesium to nitrites, and C. Kippenberger showed that with a dil. soln. of a nitrate, the first reduction product is a nitrite, then hydroxylamine, and finally ammonia. These primary reduction products can interact with one another to yield secondary products—nitrous and nitric oxides, nitrogen, etc. J. von Liebig stated that with cold **nitric acid**, nitric oxide is evolved, while C. Montemartini found that nitrous and nitric oxides, nitrogen, ammonia, and hydrogen are developed. The amount of ammonia produced in the reaction between magnesium and nitric acid increases with the concentration of the latter until 40 per cent. acid is reached, the quantity then decreases. Much hydrogen is formed; the mixture of this gas and nitric oxide liberated by 13 per cent. acid may be exploded by an electric spark.

J. J. Acworth and H. E. Armstrong obtained less nitric oxide and more nitrous oxide and nitrogen than is the case with cadmium or zinc. According to E. Divers, magnesium and nitric acid produce some hydroxylamine which is decomposed so rapidly as to escape detection unless some hydrochloric acid is also present. For some unknown reason sulphuric acid useful in the case of zinc is unsatisfactory with magnesium. According to P. T. Austen, magnesium burns with a white light in the vapour of nitric acid. According to W. Eidmann, many **nitrogenous substances**, when heated with magnesium, furnish magnesium nitride; and carbonitrogenous substances may give magnesium carbide as well.

J. Parkinson, P. T. Blunt, H. Schönn, and O. Emmerling obtained magnesium phosphide by heating magnesium with **phosphorus**. A. Stock and B. Hoffmann obtained magnesium phosphide by heating the metal with **phosphorus nitride**, P_3N_5 ; K. Seubert and A. Schmidt obtained phosphorus by the action of magnesium on **phosphorus trichloride**; and B. Reinitzer and H. Goldschmidt found that magnesium reacts with **phosphoryl chloride**, $POCl_3$, at ordinary temp., forming phosphorus trichloride, magnesium chloride, and phosphate, as well as a red substance which they think is an oxide of phosphorus; the reaction is very vigorous at 100° . H. Mouraour found magnesium slowly attacks soln. of **disodium hydrophosphate**; and A. Duboin found that a mixture of a mol of normal **calcium phosphate** with eight gram-atoms of magnesium reacts vigorously when heated in an atm. of hydrogen, some phosphine being formed. J. Parkinson heated to redness a mixture of magnesium filings and **arsenic** in a stream of hydrogen, and obtained a hard brown mass, which rapidly disintegrates on exposure to air. J. Parkinson prepared a similar product with **antimony** and magnesium. A. Stock and W. Dohrt obtained a

FIG. 4.—Freezing-point Curves of the Binary System Sb—Mg.

FIG. 5.—Freezing-point Curves of the Binary System Bi—Mg.

similar product. G. Grube obtained the f.p. curve shown in Fig. 4. There are two eutectics, with a maximum corresponding with **magnesium antimonide**, Mg_3Sb_2 , melting at 961° . Magnesium readily alloys with **bismuth**, and G. Grube similarly obtained **magnesium bismuthide**, Mg_3Bi_2 , melting at 715° , Fig. 5.

C. Winkler⁶ observed that a superficial layer of magnesium carbide is formed when magnesium is heated with **carbon**; and J. Parkinson observed that some carbide is likewise formed when magnesium is heated in a stream of **benzene** vapour, although **methane** and **coal gas** have very little action. C. O. V. Engler and E. Kneis have studied the action of **petroleum** on magnesium, and found no appreciable solvent action after four months' exposure in air; the impure oil may exert a solvent action. K. Seubert and A. Schmidt found **carbon tetrachloride** forms carbon when heated with magnesium. According to L. Kessler, when a spiral of burning magnesium ribbon is immersed in **carbon monoxide**, combustion ceases; but if the metal be heated in a stream of the gas, vivid combustion occurs, and a grey coating of carbide is formed on the metal. J. Parkinson noted the separation

of carbon when magnesium is heated in an atm. of carbon monoxide. C. Winkler, and H. Cretier also made observations on the reduction of carbon monoxide by heated magnesium. V. Meyer seems to have regarded this gas as neutral at an incipient white heat. J. Parkinson, and L. Kessler noted that **carbon dioxide** is reduced to carbon by red-hot magnesium. C. Winkler showed that if magnesium be moderately heated in a stream of carbon dioxide, the metal is slowly converted into carbide, and some carbon monoxide is formed; on raising the temp. to a full red heat, the metal inflames, forming magnesia and carbon. These reactions are more readily observed if the powdered metal is employed. When a mixture of magnesium and calcium carbonate is heated in a current of hydrogen, a violent explosion occurs, and magnesium carbide is formed, but no calcium. K. Brunner found that when magnesium powder is scattered over a flat dish containing solid carbon dioxide and a small amount of burning magnesium is dropped into this, the metal continues to burn, forming a grey cake, which, on treatment with water and hydrochloric acid, leaves a residue of black, flocculent carbon. S. Kappel, M. Ballo, and G. Giorgis have studied the action of water saturated with carbon dioxide on magnesium—some hydrogen is developed but no magnesium carbonate is precipitated—water alone, under the same conditions, is without action on the metal. J. von Liebig found magnesium is attacked by cold dil. **acetic acid**, and R. Lohnstein found that the solvent action of dil. acetic acid on magnesium is inhibited if potassium dichromate is added in sufficient quantity to the soln. The magnesium loses its power of dissolving spontaneously in the soln., but, if it is made the anode of an electrolytic cell, it dissolves readily. The conc. of the dichromate required to produce the passive condition increases with the conc. of the acetic acid. If soln. still takes place, the rate is greatly diminished by the dichromate. The passive condition may be destroyed by the addition of an alkali or magnesium salt of a strong acid, the rate of soln. of the active magnesium increasing with the conc. of the added salt. R. Lohnstein suggested that the phenomena are of catalytic nature. According to A. Cavazzi, the vapour of **carbon disulphide** converts red-hot magnesium into the sulphide. According to A. Rossel, magnesium reacts with incandescence when heated in air with **calcium carbide**: $2\text{CaC}_2 + 6\text{Mg} + 2\text{N}_2 + 5\text{O}_2 = 2\text{CaO} + 2\text{Mg}_3\text{N}_2 + 4\text{CO}_2$. L. Kahlenberg and H. Schlundt found that magnesium is not attacked by anhydrous liquid **hydrogen cyanide**, nor by a soln. of sulphur trioxide; on the other hand, the metal is attacked by a soln. of hydrochloric acid or fuming sulphuric acid in that liquid. W. Eidmann found that when magnesium is heated with the **cyanides** of the alkalis or alkaline earths, the metal carbide and magnesium nitride are formed; the less stable cyanides—*e.g.* those of zinc, cadmium, nickel, cobalt, lead, and copper—react with incandescence, forming the metal magnesium nitride and carbon; and the unstable cyanides—*e.g.* those of gold and mercury—first decompose into the metal and **cyanogen**, which latter reacts explosively with magnesium. A. Brochet and J. Petit found that magnesium is vigorously attacked in the cold by a soln. of **potassium cyanide**.

According to C. Winkler, **silicon** reacts with magnesium with feeble incandescence when the two elements are heated together. G. Rauter found that magnesium exerts very little action on **silicon tetrachloride**, when heated for 67 hrs. to $390^\circ\text{--}400^\circ$, although some silicon is formed; while K. Seubert and A. Schmidt say that much silicon is formed. T. L. Phipson and J. Parkinson found **silica** is reduced by magnesium when heated by the flame of a spirit lamp; C. Winkler found the reduction of the silica is attended by incandescence, and in the cooler parts of the containing vessel, bluish-grey magnesium silicide is formed, and in the hotter parts, brown amorphous silicon is formed. If an excess of silica be employed, no silicide is formed. **Silicates** were found by C. Winkler to be reduced like silica itself when heated with magnesium. J. von Liebig noted that **glass** on which magnesium has been burnt, and D. P. Smith that glass on which the metal has been fused, shows a black stain which is not removed by acids. V. Meyer found **porcelain** is strongly attacked by magnesium at an incipient white heat. According to J. Parkinson, and C. Winkler,

titanium dioxide is reduced by magnesium at a red heat, and the mass becomes incandescent—some *magnesium titanate*, but no *magnesium titanide* is formed. According to C. Winkler, **magnesium titanate**, MgTiO_3 , is not reduced by magnesium. E. A. Schneider found **titanium nitride**, Ti_3N_4 , reacts with magnesium like magnesium nitride, Mg_3N_2 , reacts with titanium. T. L. Phipson found that **zirconium dioxide** is reduced by magnesium at the temp. of an alcohol flame; C. Winkler showed that the reaction is not complete, and if it takes place in an atm. of hydrogen some magnesium hydride is formed; no *magnesium zirconide* was observed. According to C. Winkler, **cerium dioxide** is reduced to the sesquioxide or the metal according to the proportion of *magnesium ceride*; **thorium dioxide** is incompletely reduced with feeble incandescence; **germanium dioxide** is very vigorously reduced to metal; likewise **stannic oxide** and **lead dioxide** are vigorously and violently reduced to the respective metals.

According to H. Moissan, when magnesium is heated with **boron** in a neutral atm., magnesium boride, Mg_3B_2 , is formed; and with **boron sulphide**, boron and magnesium sulphide. K. Seubert and A. Schmidt say that boron is formed when magnesium is heated with **boron chloride**. T. L. Phipson, A. Geuther, H. N. Warren, A. Duboin, and L. Gattermann observed that **boron trioxide** is reduced by magnesium, forming boron, and C. Winkler obtained a mixture of boron and magnesium boride. H. Moissan has studied the reaction as a means of preparing boron. C. Winkler and L. Gattermann found fused **borax** is reduced like boron trioxide. J. Parkinson, and C. Winkler reduced **alumina** by magnesium; and the latter reduced **yttrium**, **lanthanum**, **gallium**, **indium**, and **thallium sesquioxides** in a similar way. J. Parkinson found **chromic oxide** is reduced by magnesium. W. R. Dunstan and J. R. Hill found that the immersion of the metal in one per cent. soln. of **potassium dichromate** or **chromate** furnishes **passive magnesium**, for the metal so treated and washed remained unchanged in distilled water for some hours under conditions where the untreated metal is oxidized all over. The passive metal is, however, also oxidized in about 24 hrs. A. Vyskocil also obtained passive magnesium. **Chromic acid** soln. act on magnesium tarnishing the surface. H. N. Warren found that **molybdenum oxide** reacts explosively with the element.

At a high temp. magnesium acts as a powerful reducing agent. H. N. Warren stated that magnesium does not reduce the alkali oxides and alkaline earths, but C. Winkler showed that this statement is wrong, for he found the **alkali hydroxides** and **alkali carbonates**, excepting caesium carbonate, to be readily reduced by magnesium when a mixture of the two is heated in a sealed tube or in a stream of hydrogen. The reaction is very energetic with lithium and sodium carbonates. A. Geuther, and T. L. Phipson observed the ready reduction of sodium carbonate; the latter found the reaction occurred at the temp. of an alcohol flame. C. Winkler thought that caesium carbonate was not reduced under these conditions, but the work of E. Graefe and M. Eckardt, N. N. Beketoff and A. Scherbatscheff, and of H. Erdmann and co-workers shows that caesium hydroxide or carbonate is readily reduced. **Cuprous oxide** and **silver oxide** are violently reduced by magnesium; **silver oxide** and **gold oxide** are reduced by heat without the aid of magnesium. The **alkaline earth oxides** are readily reduced by magnesium; **beryllium**, **zinc**, **cadmium**, and **mercury oxides** are reduced explosively when heated with magnesium, but **magnesium oxide** is not changed. F. E. Weston and H. R. Ellis found that magnesium reduces **aluminium oxide** when the mixture is ignited with a fuse.

Magnesium acts as a reducing agent on soln. of salts of the metals. The available evidence is sometimes contradictory. Magnesium has been said to precipitate the element from soln. of salts of copper, silver, gold, zinc, cadmium, mercury, thallium, selenium, tellurium, arsenic, antimony, bismuth, tin, lead, manganese, iron, cobalt, nickel, platinum, and palladium; to precipitate the oxide from soln. of salts of chromium, and uranium; to reduce but not precipitate soln. of salts of molybdenum, tungsten, and vanadium. This subject had been investigated by G. A. Maack.⁷

T. E. Phipson, Z. Roussin, R. Böttger, C. Scheibler, etc. A. Vyskocil found that the ordinary equation for the speed of heterogeneous reactions cannot be applied to the reaction between magnesium and soln. of the ammonium salts, or of neutral metallic salts, since the metal first decomposes the water, and if the soln. is nearly neutral, the speed of the reaction depends to a great extent on the oxidizing or reducing power of the attacking soln. This view confirms V. Kistiakowsky's observations on the magnesium electrode. The anions of neutral salts in soln. act catalytically on the decomposition of water by magnesium. **Platinized magnesium** is also a powerful reducing agent; thus, according to M. Ballo, it reduces nitrobenzene in alcoholic soln. quantitatively to aniline. J. I. Michailenko and P. G. Mushinsky showed that the water of crystallization of certain salts is acted on by magnesium with the evolution of hydrogen.

According to F. Wöhler, aq. soln. of ammonium chloride or carbonate dissolve magnesium with the evolution of hydrogen; S. Kern, and D. Tommasi also found the attack is vigorous with soln. of ammonium chloride, and L. Santi, and D. Vitali stated that the double salt, $\text{Mg}(\text{NH}_4)_2\text{Cl}_4$, is formed; and H. Mouraour found soln. of various **ammonium salts**—carbonate, chloride, oxalate, and sulphide—act vigorously on magnesium, but no action was observed with soln. of ammonium fluoride. H. Mouraour attributed the specific action of soln. of the ammonium salts to their solvent action on magnesium hydroxide. D. Vitali found the action of a soln. of **hydroxylamine hydrochloride** to be analogous to that of ammonium chloride.

According to G. A. Maaack, and T. L. Phipson, cold aq. soln. of the **alkali hydroxides** do not act on magnesium, and a similar observation was made by L. Kahlenberg with *N*-soln. of sodium and potassium hydroxides. The action of soln. of various **alkali salts** has been studied. H. Mouraour found a soln. of sodium carbonate is likewise attacked by magnesium. According to M. Ballo and G. Giorgis, aq. soln. of the alkali hydrocarbonates dissolve the metal with the evolution of hydrogen. According to S. Kern, when a soln. of sodium chloride is treated with magnesium, sodium hydroxide is formed with the slow development of hydrogen. D. Tommasi, however, states that in the case of potassium chloride soln. the action is catalytic, for the potassium chloride remains unchanged, and magnesium hydroxide is formed. As indicated above, W. Hughes found that the rate of evolution of hydrogen depends on the conc. of the soln., and there is a maximum with a soln. containing 32 mols of water per mol of sodium chloride; and the existence of this maximum is taken to correspond with a specific effect of the solute on the solvent. D. Tommasi and H. Mouraour also reported that aq. soln. of **salts of the alkaline earths** are feebly attacked by magnesium with the evolution of hydrogen. D. Tommasi found that with soln. of the alkali chlorides—of potassium, sodium, and lithium

FIG. 6.—The Velocity of Attack on Magnesium by Solutions of Barium, Calcium, and Sodium Chlorides.

—magnesium furnishes hydrogen more rapidly than with water, and magnesium hydroxide is formed. H. Mouraour found soln. of sodium carbonate, acetate, and tetraborate react vigorously with magnesium, but soln. of sodium phosphate, nitrate, and thiosulphate, and potassium ferrocyanide react feebly. C. F. Roberts and L. Brown found that the hydrogen eq. of magnesium can be obtained with soln. of sodium, potassium, magnesium, barium, strontium, and calcium chlorides, but only very slowly with magnesium, and probably also potassium and sodium sulphates. The action is in general more rapid with the chlorides than with the sulphates; and the rate is dependent on the conc. of the soln., although no proportionality was observed. Fig. 6 illustrates the vol. increment of hydrogen per hour, with soln. containing

$\frac{1}{10}$ -mol. per litre of the salts named—temp. 18°–19°. The maximum velocity is more quickly attained with the more conc. soln., but the reaction is completed in about the same time. With equi-mol. soln. of the chlorides the rapidity of the reaction is completed in about the order: magnesium (fastest), barium, strontium, calcium, sodium, and potassium (slowest). H. Mouraour found that soln. of potassium sodium tartrate (Seignette's salt) and sodium nitrite are slowly attacked by magnesium, while a soln. of sodium acetate is rapidly attacked.

D. Tommasi obtained cuprous chloride, cupric oxychloride, and hydrogen, but no copper, by the action of magnesium on soln. of **cupric chloride**, and K. Seubert and A. Schmidt found neutral soln. of cupric chloride gave a large proportion of cuprous oxide; ammoniacal soln. gave cuprous oxide and copper; and acidic soln. gave only copper; D. Tommasi obtained cuprous hydroxide, copper, basic copper sulphate, magnesium sulphate, and hydrogen as a result of the action of magnesium on a soln. of **cupric sulphate**; D. Vitali obtained copper, a blue basic copper salt, and hydrogen when magnesium acts on a soln. of a copper salt—*vide* the metallic precipitation of copper. The precipitation, according to E. G. Bryant, is never quantitative. According to D. Tommasi, when a soln. of auric chloride is treated with magnesium, gold, magnesium hydroxide and chloride, and hydrogen are formed; K. Seubert found auric chloride, and silver chloride in the presence of water are reduced to the metal. F. J. Faktor obtained analogous results with **salts of silver and gold**, and D. Vitali, and A. Villiers and F. Borg stated the metals are quantitatively precipitated by magnesium from these salts.

F. J. Faktor found that when **beryllium salts** are treated with magnesium, the corresponding hydroxide is formed. Magnesium liberates hydrogen from soln. of **magnesium salts**. D. Tommasi studied the reaction with magnesium chloride; G. Lemoine with aq. soln. of magnesium nitrate, chloride, sulphate, and acetate, when basic salts are precipitated, and the amount of hydrogen evolved is nearly proportional to the amount of magnesium dissolved. H. Mouraour, G. Platner, and C. F. Roberts and L. Brown, C. Kippenberger, etc., have also studied the reaction. L. Kahlenberg found that soln. of magnesium nitrate when treated with magnesium yield nitrite and finally ammonia, which accounts for the small amount of hydrogen liberated by this salt as compared with other salts of magnesium. From soln. of magnesium acetate and iodide, magnesium also evolves hydrogen rapidly. A magnesium sulphate soln. was treated with a large excess of finely divided magnesium, but no reduction of the salt to sulphite took place. He also studied soln. of magnesium chloride in glycerol, and in alcohol. S. Kern obtained zinc hydroxide by treating soln. of zinc salts with magnesium. K. Seubert and A. Schmidt found that a soln. of zinc chloride or cadmium chloride, with magnesium, gives the metal and hydroxide with neutral and ammoniacal soln.; and the metal with acid soln.; while D. Tommasi found that a soln. of cadmium chloride furnishes cadmium, cadmium oxychloride, hydrogen, and magnesium chloride; F. J. Faktor also found **zinc and cadmium salts** give the corresponding hydroxides. With a soln. of zinc sulphate, D. Tommasi obtained zinc hydroxide, zinc, basic zinc sulphate, magnesium sulphate and hydrogen. According to H. N. Warren, zinc is precipitated by magnesium from soln. in acetic acid. According to D. Tommasi, **mercuric chloride** furnishes mercurous chloride, mercuric oxide, magnesium chloride and hydrogen. D. Vitali found hydrogen, mercuric and mercurous oxides, and mercuric oxychloride were formed with mercuric chloride soln. K. Seubert and A. Schmidt obtained with neutral and acid soln. of mercuric chloride, first mercuric chloride, and later, with neutral soln., mercury. S. Kern obtained with mercuric chloride a grey precipitate which rapidly reddened when heated. D. Vitali found that magnesium reacts with soln. of **mercuric cyanide**, forming hydrogen, mercury, hydrocyanic acid, and magnesium cyanide.

According to H. Mouraour, soln. of **sodium borate** (borax) and of **alum** are attacked by magnesium. According to S. Kern, aluminium salts are but slowly affected by magnesium. K. Seubert and A. Schmidt found that a neutral soln. of

aluminium chloride forms aluminium hydroxide, but there is no decomposition in acid soln. ; and thalious chloride forms thallium. D. Vitali also obtained aluminium hydroxide from soln. of aluminium salts. F. J. Faktor also found that soln. of **thallium salts** furnish thallium, and a soln. of thallium alum gives thallic hydroxide.

D. Tommasi found that when a soln. of **lead chloride** is treated with magnesium, lead, lead oxychloride, magnesium oxychloride, and hydrogen are formed. S. Kern found that pulverulent lead is rapidly precipitated from an aq. soln. of lead nitrate by magnesium ; K. Seubert and A. Schmidt found that soln. of lead chloride always give a precipitate of lead, while a neutral soln. of stannic chloride gives stannic hydroxide, and an acid soln., metallic tin. F. J. Faktor found soln. of **stannous and stannic salts** give the corresponding hydroxides.

D. Vitali found that when soln. of **arsenites** are treated with magnesium, arsenic, arsine, and hydrogen are produced ; and with **arsenates**, a precipitate of magnesium arsenate is formed. F. J. Faktor found soln. of **antimony salts** give black flocculent antimony, stibine, and hydrogen. Similar results were obtained by K. Seubert and A. Schmidt with soln. of arsenious and antimonious chlorides ; and acid soln. of **bismuth chloride** gave bismuth.

According to H. Mouraour, a soln. of **chrome alum** is attacked by magnesium. A soln. of **chromic chloride** was found by D. Tommasi to form chromic hydroxide, magnesium chloride and hydrogen, while K. Seubert and A. Schmidt obtained chromic hydroxide with neutral soln. of chromic chloride, and no decomposition with acid soln. According to F. J. Faktor, a soln. of **potassium dichromate** is converted magnesium to the chromate, while S. Kern stated that a soln. of potassium dichromate slowly forms magnesium chromate and potassium hydroxide. According to D. Tommasi, a soln. of **manganese sulphate** furnishes manganese hydroxide, magnesium sulphate, and hydrogen. K. Seubert and A. Schmidt found that a neutral soln. of **manganese chloride** gives manganous hydroxide, and no change occurs with an acid soln. S. Kern found manganous salts give brown manganous oxide when treated with magnesium. According to H. N. Warren, manganese is precipitated from acetic acid soln. by magnesium.

According to D. Vitali, a soln. of **ferric salt** gives hydrogen, ferrosferric oxide and metallic iron ; a soln. of a **cobalt salt** first gives a blue basic salt, and then black metallic cobalt ; and a soln. of a **nickel salt** is slowly coloured green owing to the formation of nickel hydroxide. According to D. Tommasi, a soln. of ferrous sulphate forms magnesium sulphate, hydrogen, and ferrous hydroxide when treated with magnesium ; and a soln. of ferric chloride gives, without reduction, ferric hydroxide, ferric oxychloride, magnesium chloride, and hydrogen ; he also found cobaltous chloride soln. give cobaltous hydroxide, magnesium chloride, and hydrogen. The action of magnesium on soln. of ferric sulphate has been studied by S. Sugden. S. Kern obtained ferric hydroxide from a soln. of ferric chloride. According to K. Seubert and A. Schmidt, neutral soln. of ferric chloride, cobaltous chloride, or nickelous chloride give the hydroxide, $M(OH)_2$; a similar result is obtained with cobaltous and nickelous chlorides in the presence of ammonia ; and acid soln. of ferric and cobaltous chlorides give the metal, but acid soln. of nickelous chloride remain unchanged. According to H. N. Warren, iron, cobalt, and nickel are precipitated by magnesium from acetic acid soln. of the corresponding salts. F. J. Faktor, and H. Mouraour found soln. of **potassium ferricyanide** are reduced to ferrocyanide.

K. Seubert and A. Schmidt, D. Vitali, F. J. Faktor, and A. Villiers and F. Borg found soln. of **platinum tetrachloride** give platinum quantitatively when treated with magnesium ; D. Tommasi reported the formation of magnesium hydroxide and hydrogen as well as platinum ; S. Kern stated that hydrogen, platinum, and platinum dioxide are formed when a soln. of platinum tetrachloride is treated with magnesium ; and with a soln. of a **palladium salt**, hydrogen, palladium monoxide, palladium, and palladium hydroxide are formed. A. W. Knapp showed that if magnesium powder be added to ten times its weight of water, and then to this

mixture is added such an amount of palladious chloride as contains $\frac{1}{100}$ th part of the weight of magnesium, a brisk evolution of hydrogen occurs.

As a rule, magnesium precipitates the metals from neutral aq. soln. of the salts, in some cases hydroxides or basic salts are precipitated and there is a development of hydrogen, particularly in the presence of ammonium salts. G. Platner, and E. Divers explain the evolution of hydrogen by assuming that the hydrolysis of the salt furnishes an acid which directly attacks the magnesium—*vide* the action of magnesium on cupric salts in 3. 21, 3. L. Kahlenberg gave a similar explanation for salts of the heavy metals, while H. Mouraour attributed the evolution of hydrogen to the secondary action of magnesium on water. A. Commaille, and R. M. Caven assume that a galvanic couple is formed by the metal precipitated on the magnesium, and this decomposes the water. G. Lemoine also attributed the action of magnesium on soln. of its own salts to hydrolysis, although, as L. Kahlenberg pointed out, the reaction of soln. of magnesium salts towards indicators may be perfectly neutral at the outset, but soon after the introduction of the magnesium, it becomes alkaline, and remains so. Consequently, he does not accept the free acid hypothesis with soln. of salts of the alkalis, alkaline earths, and magnesium; but he rather assumes that the solvent water is bound to the solute in variable proportions and that if the chemical affinity between the magnesium and the soln. (regarded as a combination of solute and solvent) is sufficient to overcome the cohesion of the magnesium, the latter is attacked, hydrogen is evolved, and the other products may remain in soln. or be further decomposed into a hydroxide or basic salt. If no precipitate forms, the speed of the reaction is not diminished by a decrease in the surface of the magnesium.

Reactions of analytical interest.—Magnesium salts are colourless; they do not give any distinctive flame reaction; but they have a characteristic influence on the absorption spectrum of purpurin, hæmatoxylin, etc.⁸ Soln. of magnesium salts do not give a precipitate with hydrochloric acid, nor with hydrogen sulphide. Neither **ammonium sulphide** nor **ammonium hydrosulphide** gives a precipitate with soln. of magnesium salts; but if the ammonium sulphide contains free ammonia, a precipitate may be formed. Aq. ammonia produces a precipitate of magnesium hydroxide provided ammonium salts be absent; about half the magnesium will be so precipitated, and the other half forms a soluble double salt, $(\text{NH}_4)_2\text{MgCl}_4$. According to F. Jackson,⁹ the sensitiveness of the test with aq. ammonia in the absence of ammonium salts is 1 : 32000. P. Harting gave a sensitiveness of 1 : 4000. Aq. ammonia in the presence of ammonium salts gives no precipitate because of the formation of this double salt. Several other salts of the bivalent metals behave similarly—*e.g.* salts of zinc, manganese, iron, cobalt, and nickel; the trivalent metals do not form these ammonium salts. In the absence of other ammonium salts, **ammonium carbonate** precipitates a basic carbonate, say, $\text{Mg}_4(\text{CO}_3)_3(\text{OH})_2$, but usually only after boiling or long standing; the composition of the precipitate, however, depends on the temp. and conc. of the soln.; the carbonates of the alkalis behave similarly. According to F. Jackson, the sensitiveness of the test with ammonium carbonate is 1 : 200; and with sodium carbonate, 1 : 4000. Magnesium salts give no precipitate with **barium carbonate** at ordinary temp., but with long-continued boiling, magnesium is completely precipitated from soln. of the sulphate, and partially precipitated from a soln. of the chloride or nitrate. A soln. of **barium hydroxide** likewise precipitates magnesium almost quantitatively as hydroxide, provided ammonium salts be absent; the hydroxides of the alkalis and alkaline earths behave similarly. No precipitation occurs with soln. of **hydrochloro-platinic acid**, with **sodium cobaltic nitrite**, with **hydrofluosilicic acid**, with **potassium chromate**, or with **sulphuric acid**. An **alkali phosphate** or **ammonium phosphate** is a characteristic reagent for magnesium; it produces in soln. containing ammonium chloride, and even free ammonium hydroxide, a white crystalline precipitate of ammonium magnesium phosphate, $\text{Mg}(\text{NH}_4)\text{PO}_4$; very dil. soln. give a precipitate only after long standing. When the precipitate is calcined, it

forms magnesium pyrophosphate, $\text{Mg}_2\text{P}_2\text{O}_7$, in which form the magnesium can be weighed. According to F. Jackson, the sensitiveness of the test with disodium hydrophosphate is 1:128000; and, according to P. Harting, with ammonium phosphate 1:200000. The **alkali arsenates** behave like the phosphates and give a precipitate of ammonium magnesium arsenate, $\text{Mg}(\text{NH}_4)\text{AsO}_4 \cdot 6\text{H}_2\text{O}$, which, on ignition forms magnesium pyroarsenate, $\text{Mg}_2\text{As}_2\text{O}_7$. If the soln. of magnesium salt be sufficiently dil., and a large proportion of ammonium chloride be present, no precipitation occurs with **ammonium oxalate**. A soln. of an **alkali acetate** gives no precipitate with magnesium salts. With **potassium ferrocyanide**, a cold dil. soln. of magnesium salts gives a white crystalline precipitate of potassium magnesium ferrocyanide after standing some time; conc. soln. give a precipitate immediately; if ammonium salts are present the triple salt ammonium potassium magnesium ferrocyanide is formed. According to F. G. Schlagdenhauffen,¹⁰ the presence of 0.02 per cent. of magnesium sulphate or chloride can be detected in salts of the alkaline earths by a soln. of so much iodine in a 2 per cent. soln. of sodium or potassium hydroxide that the liquid has a golden-yellow colour. A red coloration or a brownish-red precipitate is formed, which, according to T. Rettie, has no definite composition, and is probably a mixture of iodine with magnesium hydroxide. Lithium salts do not give the reaction. According to L. Grimbert, the original soln. is unstable, and not so sensitive as the soln. made by adding a few c.c. of a 10 per cent. soln. of potassium iodide to the liquid under examination, and then adding one or two drops of a soln. of sodium hypochlorite (*eau de Javal*). J. Bellier recommends using a one per cent. soln. of potassium iodide sat. with iodine; followed by a soln. of sodium hydroxide. According to L. Grimbert, the reaction is not so sensitive as the ammonium phosphate test, and the sensitiveness is 1:2000, while, according to J. Bellier, it is 1:20000.

The atomic weight of magnesium.—The hydrogen eq. of magnesium is about 12. J. J. Berzelius¹¹ assigned the formula MgO to the oxide. There was some discussion as to whether the formula was Mg_2O , MgO , MgO_2 , or Mg_2O_3 , with the corresponding at. wt. of the order of 12, 24, 48, or 36 respectively. The formula MgO was finally adopted because the corresponding at. wt. of magnesium is in harmony with J. H. van't Hoff's extension of Avogadro's rule; with Dulong and Petit's rule; with Mitscherlich's isomorphism rule; and with its position between zinc and beryllium in Mendeléeff's periodic table. T. Thomson discussed the at. wt. of magnesium in 1821.

The ratio $\text{MgSO}_4 : \text{BaSO}_4$.—J. J. Berzelius made the first at. wt. determination of magnesium in 1812, by weighing the SO_3 , in a given quantity of magnesium sulphate, as barium sulphate, and from the ratio $\text{MgSO}_4 : \text{BaSO}_4$ he computed an at. wt. 25.24, when oxygen 16 is taken as unit. J. L. Gay Lussac likewise used this method in 1819, and obtained 23.62; T. Scheerer, in 1846, 24.16, and in 1847, 24.20; V. A. Jacquelin, in 1851, 24.43; and A. Macdonnell, in 1852, 24.30.

The ratio $\text{MgO} : \text{MgSO}_4$.—J. J. Berzelius synthesized the sulphate, and from the ratio $\text{MgO} : \text{MgSO}_4$, obtained the at. wt. 24.20; and in 1826, 25.28; V. A. Jacquelin, in 1851, obtained 24.44; L. Svanberg and O. Nordenfeldt, in 1848, 24.71; J. F. Bahr, in 1852, 24.77; and J. C. G. de Marignac, in 1883, 24.372.

The ratio $\text{MgSO}_4 : \text{MgO}$.—V. A. Jacquelin, in 1851, calcined magnesium sulphate at a high temp. so as to convert it into the oxide, and from the ratio $\text{MgSO}_4 : \text{MgO}$, he computed an at. wt. 24.44; and J. C. G. de Marignac, in 1883, obtained 24.363. A. Macdonnell, in 1852, determined the ratio $\text{MgSO}_4 \cdot 7\text{H}_2\text{O} : \text{MgO}$ from which he calculated the at. wt. 24.30.

The ratio $\text{MgC}_2\text{O}_4 \cdot 2\text{H}_2\text{O} : \text{MgO}$, or $\text{MgCO}_3 : \text{MgO}$.—L. Svanberg and O. Nordenfeldt determined the ratio $\text{MgC}_2\text{O}_4 \cdot 2\text{H}_2\text{O} : \text{MgO}$, by calcining the oxalate, and hence computed the at. wt. 24.72. R. F. Marchand and T. Scheerer, in 1850, likewise calcined the carbonate, and from the ratio $\text{MgCO}_3 : \text{MgO}$, calculated the at. wt. 24.04; and, in 1858, T. Scheerer obtained the value 24.01.

The ratio $\text{MgCl}_2 : 2\text{Ag}$, or $\text{MgCl}_2 : 2\text{AgCl}$.—In 1859, J. B. A. Dumas determined

the chlorine in a soln. of magnesium chloride by titration with a standard soln. of silver nitrate, and from the ratio $\text{MgCl}_2 : 2\text{Ag}$ computed the at. wt. 24.63; and T. W. Richards and H. G. Parker, in 1896, 24.362. The last-named also converted the chlorine of the magnesium chloride into silver chloride, and from the ratio $\text{MgCl}_2 : 2\text{AgCl}$, computed the at. wt. 24.373.

The ratio $\text{Mg} : \text{MgO}$.—W. M. Burton and L. D. Vorce, in 1890, converted magnesium, distilled in vacuo, into the nitrate, and then calcined the nitrate to convert it into the oxide; from the ratio so obtained, they computed the at. wt. 24.29. T. W. Richards and E. F. Rogers showed that important errors are likely to accrue owing to the occlusion of gases by magnesium oxide obtained by the ignition of salts, etc.

F. W. Clarke's calculations averaged 24.398, and B. Brauner's 24.36. The best representative value for the at. wt. of magnesium, according to the International Table, 1922, is 24.32. The atomic number is 12. A. J. Dempster claimed to have resolved magnesium vapour into isotopes of at. wt. respectively 24, 25, and 26, and in the proportions 6 : 1 : 1.

§ 6. Magnesium Oxides and Hydroxide

In 1866, E. Beetz¹ prepared what he regarded as **magnesium suboxide** as a black deposit on the positive pole during the electrolysis of a soln. of magnesium sulphate or sodium chloride with magnesium electrodes—hydrogen is given off at both electrodes. If the current is arrested, the black substance forms white flecks in the electrolyte. According to G. Bobarovsky, the best yield is obtained by working with a high current density, at a low temp., and for a short period with soln. of sodium or potassium chloride, or magnesium chloride or sulphate, and particularly with an alcoholic soln. of potassium acetate—the black product is not obtained with alkali hydroxides or ammonium salt soln. F. C. Frary and H. C. Berman obtained the suboxide by electrolyzing magnesium and potassium chlorides in a graphite crucible. They added that it is not formed when oxygen is completely excluded from the electrolyte, by melting the mixture in a stream of hydrogen chloride, and continuing the passage of the gas during electrolysis. The addition of a little magnesium oxide to the electrolyte results in the formation of the suboxide.

G. Gore found that if magnesium in contact with platinum be dipped in a soln. of glacial acetic acid in absolute alcohol, the black deposit appears in a few hours, and grows thicker for a few days. The product is formed more slowly if magnesium in contact with platinum, palladium, iron, gold, or silver, be dipped in water in the presence of carbon dioxide, coal gas, carbon tetrachloride, or ethylene tetrachloride, but not with carbon disulphide. The black product is indeed formed if the foreign metal is not employed. S. Kappel obtained a black substance by passing a stream of air over magnesium in contact with ammonia. A. K. Christomanos also obtained a black deposit when a cold substance was introduced into the flame of burning magnesium.

The black deposit, said G. Bobarovsky, appears to be homogeneous under the microscope; and his analyses range from Mg_3O_5 to Mg_3O_2 . G. Gore's product became white when heated. E. Beetz found that the suboxide decomposes water with the evolution of hydrogen, and the formation of a white precipitate—possibly magnesium hydroxide. According to F. C. Frary and H. C. Berman, the hydrogen is contaminated with 5 per cent. of nitrogen. E. Beetz found the black substance dissolves in acids with the evolution of hydrogen and the formation of a salt of ordinary bivalent magnesium. With aq. soln. of magnesium sulphate it forms basic magnesium sulphate, and it is soluble in aq. ammonium chloride. According to F. C. Frary and H. C. Berman, the black substance is without action on a soln. of anhydrous nickel chloride in absolute alcohol, whilst metallic magnesium rapidly precipitates nickel.

Magnesium oxide, MgO .—This oxide has also been called *magnesia*, *calcined magnesia*, *burnt magnesite*, *Talkerde*, *Bittererde*, *magnesia usta*, *magnesia calcinata*, *magnésie*, etc. It was discovered by A. Scacchi² at Monte Somma, Vesuvius, as a mineral, contaminated with more or less ferrous oxide, and called *periclase*—*περίκλας*, about; *κλάσις*, fracture—in allusion to the cleavage. The mineral has also been found at Teulada (Sardinia), Leon (Spain), Predazzo (Tyrol), Nordmarken (Norway) and Langban (Sweden), Pulpit Rock (Tasmania), etc. Analyses have been reported by A. Damour, H. St. C. Deville, E. Heydecke, and others.

Magnesium oxide is a product of the oxidation of the metal. The oxide is also produced in the amorphous or crystalline form by the calcination of many of the salts of magnesium—e.g. the carbonate, sulphate, nitrate, etc. It is also made commercially for the manufacture of magnesia bricks by the calcination of magnesite

in kilns of various kinds—*vide* lime. W. C. Riddell and C. N. Schuette described a shift kiln for making caustic calcined magnesite. O. Schumann³ also made it by the calcination of magnesium sulphide in a current of steam. Magnesium oxide is made by heating the chloride in a stream of moist air, or flue gas: $2\text{MgCl}_2 + 2\text{H}_2\text{O} = 4\text{HCl} + 2\text{MgO}$. This process has been studied by T. J. Pelouze, E. Solvay, C. Heinzerling and J. Schmidt, and by the Salzbergwerk Neu-Stassfurt; F. Konther made magnesia by heating magnesium chloride with calcium chloride when hydrogen chloride is formed, and the magnesium salt is transformed into the oxide, the remaining calcium chloride can be removed by leaching with water. H. P. Bassett converted the chloride into oxide by heating it with steam at about 480° – 650° , and removing any chlorine compounds by washing.

The extraction of magnesia from sea-water has been discussed by T. Schlösing. Processes for the recovery of magnesia from magnesium chloride soln., kainite or carnallite lye, etc. have been patented by M. Schliephacke and H. Riemann, and Ramdohr, Blumenthal u. Co., Alkaliwerke Westeregeln, A. Feldmann, G. Rosenthal, R. Heinz, M. von Maltzan, A. Rümpler, A. Vogt, etc. A. Rümpler devised a process for the recovery of magnesia from beet sugar residues; and C. J. Johanson, from mineral water residues. E. W. von Siemens and J. G. Halske patented a process for the recovery of magnesia from ferruginous magnesian minerals and silicates by calcination in a stream of sulphur dioxide and air, whereby the magnesium alone forms soluble sulphate. H. Holland, G. Mojon, and E. Priwoznik have discussed the extraction of magnesia from serpentine rocks.

G. d'Adelswärd patented a process for *the separation of magnesia from dolomite* involving the soln. of the carbonate in hydrochloric acid, and its subsequent precipitation with calcium hydroxide. J. B. M. P. Closson treated dolomite with an aq. soln. of magnesium chloride: $\text{CaCl}_2 + \text{MgCl}_2 + \text{CaO} \cdot \text{MgO} = 2\text{CaCl}_2 + 2\text{MgO}$. A small quantity of sugar or molasses greatly accelerates the decomposition. A compound of sugar and lime is produced, from which, by the action of magnesium chloride, calcium chloride, magnesia, and sugar are formed. The last again acts on more of the calcined dolomite, with the formation of the soluble sugar-lime, and so on. From the liquid finally obtained the sugar is removed as the insoluble tribasic sugar-lime compound by heating. C. Bernard and L. Ehrmann, and C. Scheibler proposed to extract lime from calcined dolomite by means of a soln. of sugar. The solubility of lime in this menstruum is high, and of magnesia, low. O. Henry slaked the calcined dolomite with water, and treated it with half the amount of pyroligneous acid or hydrochloric acid necessary to dissolve the whole. The lime was thus removed by "elective affinity," and the washed residue consisted of magnesia. T. Twynam also digested raw dolomite with pyroligneous acid, and found that the magnesia is first taken up, and then precipitated; the calcium acetate soln. was decanted off. R. T. Stull found that by treating calcined dolomite with just sufficient sulphuric acid to combine with the contained lime, the magnesia content could be raised from 42 to 75 per cent. R. D. Pike said that the lime is reduced by agitating the calcined mineral in a closed vessel at 300° – 600° in presence of a gas containing carbon dioxide and water vapour, and afterwards leaching with water.

According to G. Lemoine, by digesting dolomite with water charged with carbon dioxide, the magnesium carbonate dissolves more rapidly than the calcium carbonate. When the soln. is heated, the magnesium carbonate is precipitated, and the carbon dioxide which is evolved can be used over again; G. Moressée also found that when calcined dolomite is powdered and suspended in water at 10° , through which carbon dioxide, at 5–6 atm. press., is passed, only the magnesium oxide is dissolved. The extraction of magnesite from dolomite by the fractional soln. with carbonic acid has been also investigated by F. Findeisen, and H. L. Pattinson. C. Kippenberger based a technical process for the decalcification of dolomite, and the preparation of magnesium carbonate from magnesite, bitter spar, and from kainite or carnallite liquors, upon the fact that alkali hydrocarbonate soln. do not dissolve ferric hydroxide or calcium carbonate. The mineral is powdered, dissolved in commercial hydrochloric acid, and the iron oxidized by warming gently with a

little nitric acid. The soln. is then precipitated with sodium carbonate in slight excess, the filtered precipitate shaken with a sufficiently strong soln. of alkali bicarbonate, and the soln. filtered after the lapse of 20 minutes, and set aside to crystallize. The mother liquor can be used again and again for the extraction.

A cheap process for the **decalcification of dolomite** would make the large deposits of dolomite available for the manufacture of magnesia firebricks. Processes involving the use of chemicals would probably make the cost rather too high for the recovered magnesia to compete with imported magnesite. Physical methods of separation based on (i) the difference in the sp. gr. of the lime and magnesia when calcined at a high temp.; and (ii) the greater inertness of magnesia when the calcined mass is treated with water, do not give a good separation, although F. Findeisen recommended such a process in 1860, and H. Auzies and A. Segoffin have patented a process for the decalcification of dolomite by slaking and levigating calcined dolomite in a series of tanks. The magnesium hydroxide being lighter than the calcium hydroxide is carried further by the water. They said that the deposit in the tank is nearly pure magnesium hydroxide. The method was examined by J. W. Mellor. L. H. Duschak found the best calcination temp. is 900° – 950° , and the water used for leaching should be free from carbon dioxide. If the dolomite has been calcined at a higher temp., and especially if "dead burnt," the extraction is very incomplete, and is not improved by fine grinding owing to the formation of an insoluble compound. R. T. Stull treated calcined dolomite with running water, and raised the magnesia content from 42 to 65 per cent.; boiling the calcined dolomite with water, and running off the magnesium hydroxide by flotation raised the magnesia content from 42 to 65–75 per cent. H. G. Schurecht and D. Eyoub, and T. Simon also made some observations on this subject. W. Esch said that calcium oxide is leached from hot calcined dolomite by a soln. of calcium chloride; and R. A. W. Black, by a soln. of carbon dioxide in water made alkaline with calcium hydrocarbonate.

J. J. Ebelmen obtained crystals of periclase by melting together lime and magnesium borate in a porcelain oven; A. Daubrée, by decomposing magnesium chloride by lime at a red heat; J. B. A. Dumas, by melting magnesium chloride; H. Debray, by melting a mixture of magnesium and potassium sulphates; H. St. C. Deville, by acting on red-hot magnesia with a slow current of hydrogen chloride; A. Cossa, by strongly heating a mixture of magnesium sulphate and sodium chloride; F. Fouqué and A. Michel-Levy, by acting on red-hot magnesium chloride with steam; T. Hiortdahl, by melting magnesium chloride with silica and zirconia; A de Schulten, by slowly cooling a molten mixture of potassium hydroxide and magnesia; A. le Royer, A. Brun, and M. Collet, E. Sommerfeldt, F. Heussler, and H. Moissan, by heating magnesite in an electric arc furnace; M. Houdard, by heating a mixture of magnesia with five times its weight of magnesium sulphide in a carbon crucible in an electric arc furnace; and G. Brügelmann, by calcining the nitrate or hydroxide, not the carbonate, in a covered platinum crucible. J. Meunier prepared crystals by dissolving magnesia in hydrochloric acid, and after evaporating the soln. heating it until hydrogen chloride ceases to be evolved. When the product is heated to redness, the trace of hydrogen chloride which remains acts as a mineralizer, and "brilliant octahedrons and tetrahedrons of periclase deposit on the walls of the crucible and cover." R. Otto and J. H. Kloos found crystals of periclase in a kiln lined with magnesia blocks, and used for preparing chlorine from magnesium chloride. Periclase is also found in magnesia bricks which have been used as linings in high temp. furnaces.

H. Struve⁴ found *magnesia usta* contained traces of ammonium nitrate, but no peroxide; and H. Rose found that the product obtained from *magnesia alba* containing chlorine, still retained chlorine. In general magnesia prepared by the calcination of magnesite will retain the non-volatile impurities of the original. T. W. Richards and E. F. Rogers found that magnesium oxide prepared by calcina-

tion is far more prone to occlude gases during ignition than is the case with zinc, copper, cadmium, or nickel oxide. The amount varied from 0.5 to 1.9 c.c. of gas per 10 grms. of magnesium oxide, and the gas contained oxygen, nitrogen, and carbon dioxide—in one case respectively in the proportions 38.9, 58.9, and 2.2 per cent. According to J. Meunier, magnesia may be freed from calcium by igniting at a red heat and subsequently, after cooling, extracting with successive portions of a 10 per cent. soln. of sucrose, until the last extract does not give a turbidity with ammonium oxalate. The residue is then washed and dried. If further purification is desired, this material is dissolved in hydrochloric acid and the soln. evaporated to dryness. The residue is gradually heated to 800°–900° in a covered crucible, and magnesia is obtained in its crystalline form as periclase on the lid and sides of the crucible and on the surface of the amorphous magnesia in the crucible.

V. Kohlschütter and J. L. Tüscher⁵ prepared colloidal magnesium oxide dispersed in a gaseous medium by making the metal one electrode of an electric arc, and oxidizing the vapour.

The physical properties of magnesium oxide.—V. Kohlschütter and J. L. Tüscher⁶ obtained highly dispersed magnesia, without a solvent, by volatilizing the metal in an electric arc, and suddenly cooling the vapour by a current of air. The precipitation of the fume was effected by a high-tension electric field. The crystals of magnesium oxide, and periclase, belong to the cubic system. F. Rinne believes that there is a hexagonal modification of magnesium oxide. According to W. P. Davey and E. O. Hoffman, E. Schiebold, W. Gerlach and O. Pauli, A. W. Hull, R. W. G. Wyckoff and J. A. Hedvall, **X-radiograms** of crystals of magnesia exhibit a simple cubic lattice of the sodium chloride type with sides 4.220 ± 0.02 Å. W. L. Bragg gives for the distance between the neighbouring atom centres as 2.11 Å. J. A. Hedvall examined the X-ray spectra of magnesia prepared in different ways, and found no change in the structure to be produced by heating. According to A. Scacchi, the **specific gravity** of the mineral (natural crystals) is 3.75; A. Damour gave 3.674; A. Cossa, 3.642 at 12°; H. M. Goodwin and R. D. Mailey, 3.674 (20°); and A. Sjögren, 3.90. For the artificial crystals, J. J. Ebelmen gave 3.636; A. de Schulten, 3.566; E. Mallard, 3.50; R. Otto and J. H. Kloos, 3.555 to 3.571; M. Houdard, 3.579 at 0°; and E. Madelung and R. Fuchs, 3.466–3.476 (0°). The sp. gr. of the amorphous, white, voluminous powder was given by C. J. B. Karsten as 3.2; by J. B. Richter as 3.07; by R. Kirwan as 2.3; and by G. Brügelmann as 3.42; H. Beckurts found the sp. gr. of *magnesia usta levis*, obtained by calcining light magnesia alba, to be 2.74; that of *magnesia usta*, obtained by calcining heavy magnesium carbonate, to be 3.057; and that obtained from neutral magnesium carbonate, to be 3.69. The sp. gr. of amorphous magnesia depends upon the temp. of calcination, thus, A. Ditte found:

	350° (1 hr.)	440° (1 hr.)	c. 560° (1 hr.)	c. 1200° (12 hrs.)
Sp. gr. at 0° . . .	3.1932	3.2014	3.2482	3.5692
Sp. gr. at 100° . . .	3.0971	3.1263	3.1909	3.5131

H. Rose showed that the sp. gr. of amorphous magnesia was raised to 3.647 near that of the natural mineral after calcination in a porcelain oven—temp. near 1600°. H. Moissan further found that when magnesia is heated for 2 hrs. in a blast, with retort carbon as fuel, the sp. gr. at 20° was 3.577; when heated 2 hrs. in the electric arc, 3.587; and when heated in an electric crucible furnace, 3.654. H. M. Goodwin and R. D. Mailey gave 3.493 for the sp. gr. of fused magnesia at 20°. In some cases—G. Brügelmann, and K. Arndt—the sp. gr. of amorphous magnesia is stated to be greater than that of the crystalline or fused material—there is always a possibility that minute air blebs entangled in the fused material will spoil the observations. J. W. Mellor suggested the possibility of estimating the proportion of α -magnesia (low sp. gr. form) and β -magnesia (high sp. gr. form) in a given sample of burnt magnesite from the observed sp. gr., and the following data give an idea of the

rate of conversion from the presumably amorphous to the presumably crystalline variety. After a two hours' calcination between 1300° and 1350° ,

Number of calcinations	1	2	3	4	5	6
Sp. gr.	3.16	3.32	3.46	3.54	3.59	3.60
Per cent. converted	—	26	54	70	78	80

V. Tadokoro found the sp. gr. of magnesia brick at different temp. to be

	20°	100°	200°	400°	600°	800°	1000°
Sp. gr.	2.295	2.291	2.285	2.266	2.247	2.231	2.213

The **hardness** of periclase is approximately 6 on Mohs' scale; the artificial crystals prepared by R. Otto and J. H. Kloos had a hardness between that of felspar and of quartz; and J. J. Ebelmen's crystals a hardness of 4. A. Reis and L. Zimmermann have discussed this subject. E. Madelung and R. Fuchs gave $0.70\text{--}0.80 \times 10^{-4}$ megabars per sq. cm. for the **compressibility** of artificial magnesia.

According to L. B. Guyton de Morveau,⁷ magnesia fuses with difficulty in a fire fed with oxygen, and its surface has after cooling the appearance of a porcelain glaze. In 1802, R. Hare fused magnesia in the oxyhydrogen blowpipe flame, and in 1819 E. D. Clarke also found that magnesia is converted by the oxyhydrogen blowpipe flame into a kind of opaque glass, which scratches glass like the diamond. H. Davy also fused magnesia under the influence of a powerful voltaic current. H. Moissan fused magnesia in an electric arc furnace whose temp. was estimated to be 3000° . K. Arndt gives 2500° for the **melting point** of purified magnesia, and he said that magnesia cannot be melted in the oxyhydrogen flame unless it be contaminated with silica, iron oxide, etc. H. M. Goodwin and R. D. Mailey found that fragments of pre-fused oxide did not fuse or soften below 1890° ; but above 1940° , the grains always fused together, and it was considered that 1910° may be taken as the approximate m.p. of the fused oxide—this temp. appears rather low, indicating that the oxide was not of a high degree of purity. W. Hempel found Veitsch magnesite fused at 1825° – 1830° ; and magnesia at 2250° ; A. Lampen found that fused magnesia had a m.p. of 2000° ; and a magnesia brick with a high percentage of iron at 1900° had its edges rounded, and was quite fused at 2000° . C. W. Kanolt gave $2800^{\circ} \pm 13^{\circ}$ for the m.p. of magnesia; and O. Ruff, 2500° ; and O. Ruff and P. Schmidt, 2800° in an atm. of nitrogen. H. Caron stated that magnesium oxide cannot be fused in a wind furnace at a white heat, but in the oxy-coal-gas flame, it melts, and partially volatilizes. E. Tiede and E. Birnbräuer could not melt magnesia, but said that volatilization begins at about 2000° . A. A. Read did not detect any change when magnesium oxide is heated to the m.p. of platinum. C. Despretz claimed that by the simultaneous action of a current from 185 Bunsen's cells, the burning glass, and a hydrogen flame, he was able to volatilize magnesia; and P. Lebeau has stated that magnesia boils vigorously when heated seven minutes by a current of 110 volts and 700 amps., and that the volatilization of the oxide is much faster in the presence of three or four times its weight of sugar charcoal—possibly owing to the intermediary formation of magnesium or magnesium carbide, for R. E. Slade has shown that magnesia can react with carbon at a temp. below the m.p. of the oxide. O. Ruff and P. Schmidt measured the **vapour pressure** of magnesia. According to O. Ruff and O. Goecke, the **sublimation temperature** at one atm. press. is about 2000° , and W. R. Mott estimated the **boiling point** to be 3600° ; O. Ruff and P. Schmidt found 2800° – 2850° in an atm. of an indifferent gas at 760 mm. E. Tiede and E. Birnbräuer found that magnesia dissociates readily at 1900° in a vacuum furnace producing a deposit of magnesium. E. W. Washburn computed the **latent heat of fusion** to be 30,000 cal. per mol, or 700 (± 15 per cent.) cal. per gram.

H. V. Regnault found the **specific heat** of artificial magnesium oxide to be 0.24394 between 24° and 100° ; and A. S. Russell found 0.1006 between -79.3° and -190.8° ; 0.1933 between 0° and -79° ; and 0.2385 between 1.4° and 48.6° . H. von Wartenberg and G. Witzel found the mol. ht. of magnesium oxide at 2780°

to be 11·6 cals. Observations were also made by W. Steger, and E. Heyn and co-workers. V. Tadokoro found the mean sp. ht. of a magnesia brick to be

Sp. ht.	218°	303°	382°	480°	579°	687°	796°	894°
	0·223	0·238	0·254	0·263	0·266	0·265	0·264	0·263

It is not clear if the decrease at the more elevated temp. is due to errors of experiment. Measurements of the sp. ht. at a low temp. were made by A. Magnus. H. M. Goodwin and R. D. Mailey found the linear **coefficient of thermal expansion** of fused magnesia at θ° between 120° and 270° , to be $\alpha=0\cdot00001140+0\cdot0000000092(\theta-120)$, a value not much greater than that for a quartz crystal cut parallel to its optical axis, and nearly equal to that of platinum. H. Fizeau found $\alpha=0\cdot00001043$ for the coeff. of expansion of periclase, and for the increase per degree rise of temp. $da/d\theta=0\cdot0000000267$. J. W. Mellor found $\alpha=0\cdot0000126$ for magnesite bricks between 15° and 1350° ; H. J. Hodsman and J. W. Cobb obtained $0\cdot00001274$ for the coeff. of expansion of a magnesia brick between 15° and 1000° . B. Bogitch measured the expansion of magnesia bricks. V. Tadokoro found the mean coeff. of expansion of a magnesia brick to be

Coeff. exp.	20°	100°	200°	400°	600°	800°	1000°
	0·04000	0·04063	0·04131	0·04142	0·04126	0·04125	0·04128

R. S. Hutton and J. R. Beard found that fused magnesia, powdered to pass a sieve with 600 meshes per sq. cm., had a **thermal conductivity** between 20° and 100° $k=0\cdot00047$ cal. per sq. cm. degree difference of temp., per second; against $k=0\cdot00029$ for lime; and $k=0\cdot00028$ for firebrick. He also found for a magnesia firebrick $0\cdot00050$; for calcined Greek magnesite, $0\cdot00045$; for calcined Styrian magnesite, $0\cdot00034$; and for lightly calcined magnesite, $0\cdot00016$. S. Wologdine found $0\cdot0065$ and $0\cdot0055$ for two magnesite bricks with respectively 41 and 35·1 per cent. porosity. B. Dudley obtained $0\cdot0343$ for the mean conductivity of a magnesia brick over the range from 445° to 830° . C. Dougill, H. J. Hodsman, and J. W. Cobb found the conductivity of a magnesite firebrick fell from $K=0\cdot017$ at 380° to $0\cdot0132^\circ$ at 700° to $0\cdot00000091$ at 1370° . V. Tadokoro found the thermal conductivity of a magnesia brick to be

Conductivity $\times 10^3$	200°	300°	400°	500°	600°	700°	800°	900°
	6·57	5·47	4·91	4·71	4·39	4·14	3·85	3·73

The **heat of formation** of magnesium oxide, according to J. Thomsen, is (Mg, O), 145·86 Cals.; H. von Wartenberg gave 143·9 Cals. According to the former, the heat of formation of magnesium hydroxide is (Mg, O, H_2O), 148·96 Cals., and (Mg, O_2 , H_2), 217·32 Cals.; M. Berthelot gave respectively 148·8 and 217·8 Cals.; and for (MgO, H_2O), he gave 5·4 Cals. M. Berthelot also measured the heat of precipitation of magnesium hydroxide by adding a soln. of ammonia or sodium hydroxide to a soln. of a magnesium salt. J. Johnston gives for the free energy of the change hydroxide to oxide, 3600 cal. at 25° . According to A. Ditte, the **heat of the solution**, in sulphuric acid, of magnesia calcined at different temp. is very different:

Temp. calcination	350°	440°	c. 560°	c. 1200°
A. Ditte	832·8	920·8	961·7	1004·6 cal.
J. C. G. de Marignac	—	874	875	867 cal.

J. C. G. de Marignac examined what he called *l'influence prétendue* of calcination on the heat of soln., and his data are indicated along with those of A. Ditte.

E. Mallard⁸ gave for the **index of refraction** of artificial crystals 1·7307 for Li-light, 1·7364 for Na-light, and 1·74133 for Tl-light; S. Sommerfeldt, 1·7298 for red light, 1·7350 for Na-light, and 1·7460 for blue light; A. Le Royer, A. Brun, and L. W. Collet gave 1·700 for red light, and 1·717 for green light. According to D. Brewster, H. Caron, and C. M. T. du Motay and C. R. M. de Maréchal, at a high temp. magnesia has a very high emissive power for light; the light is not very different from that of burning magnesium. F. Henning and W. Heuse studied the

reflecting power of magnesia. J. Drummond tried magnesia in place of lime for the lime-light, but found the intensity of its illumination to be less than half that of lime. H. E. Ives and co-workers studied the illuminating power and emissivity of mantles made of magnesia and heated by Bunsen's flame. The results compare favourably with those of thoria. W. Crookes, and H. Jackson found magnesia has a marked reddish **fluorescence** in the cathode rays, and L. de Boisaubrand found the fluorescence is a bright red if the magnesia has about one per cent. of chromium. P. Bary found that magnesia does not phosphoresce when exposed either to the **X-rays** or to **Becquerel's rays**. E. L. Nichols and D. T. Wilber found that magnesium oxide, like calcium oxide, exhibits **flame luminescence**. E. L. Nichols studied the brightness of the luminescence, and found that when heated to 1000° in the oxyhydrogen flame magnesia appears blue. W. W. Coblentz found a transparent region in the **ultra-red transmission spectrum** at 5μ , preceded and followed by almost complete opacity. The bands at 3.3μ and 3.8μ are virtually the same as those of calcite. The **ultra-red reflection spectrum**, like that of calcite, has maxima at 6.5μ and 6.8μ . E. L. Nichols found the **colour temperature** of incandescent magnesia is 5000° , while the actual temp. is not over 2000° .

According to F. Beijerinck,⁹ periclase is a non-conductor of electricity at ordinary temp. H. M. Goodwin and R. D. Mailey found the specific **electrical conductivity** of small cylinders of fused magnesia at different temp. in mhos :

Sp. conductivity $\times 10^6$	700°	800°	900°	1000°	1050°	1100°	1150°	1500°
	—	0.01	0.10	0.20	0.34	1.00	2.60	85.0-

The results are plotted with those of porcelain in Fig. 7. Fused magnesia is thus

FIG. 7.—Specific Conductivity of Porcelain and Fused Magnesia.

A. A. Somerville found that a column of the oxide 1 cm. diam. and 10 cms. long has an electrical resistance of 10^7 ohms at 545° . According to F. Horton, the effect of temp. on the

electrical conductivity (mhos) of magnesia is

	471°	630°	828°	1055°	1191°	1204°	1341°
Ohms	35×10^6	8×10^5	88000	12450	4900	12900	29×10^4
Mhos	3.69×10^{-9}	1.61×10^{-7}	1.46×10^{-6}	1.04×10^{-5}	2.63×10^{-5}	1.00×10^{-5}	4.45×10^{-7}

The electrical conductivity of magnesium oxide thus increases rapidly with the temp. up to 1200° – 1250° and then decreases. If the temp. is kept constant above 1200° , the conductivity also decreases with the time. The phenomenon is probably due to a change of the oxide into a less conducting form of greater density. There is evidence of a slight electrolysis during the passage of the current. F. Kohlrausch and F. Rose found the specific conductivity of a sat. soln. of magnesium hydroxide at 18° to be 83×10^{-6} mhos; and F. Kohlrausch, 69×10^{-6} to 94×10^{-6} mhos. S. Glixelli measured the **electro-osmosis** of magnesium oxide. S. Meyer gives for the **magnetic susceptibility** -0.008×10^{-6} units per mol, or -0.055×10^{-6} units per grm. E. Thomson¹⁰ has studied the orientation of fine particles of magnesium oxide in the magnetic field.

The chemical properties of magnesium oxide.—As indicated above, T. W. Richards and E. F. Rogers¹¹ found magnesium oxide prepared by the ignition of the nitrate or carbonate always contained occluded gas; the gas mainly consisting of oxygen and nitrogen, with a smaller proportion of carbon dioxide. J. A. Hedvall and N. von Zweigbergh have studied the action of **barium dioxide**

on magnesia. According to H. Davy, magnesia absorbs **chlorine** at a red heat, and forms magnesium chloride with the evolution of oxygen. V. H. Veley found that while dry **hydrogen chloride** has no action on magnesia at ordinary temp., a reaction occurs at about 40°. A. J. Balard stated that calcined magnesia is not decomposed by **bromine**. L. Meyer observed that when magnesia is heated in a stream of **carbon tetrachloride**, magnesium chloride, carbon dioxide and monoxide, and carbonyl chloride are formed. P. N. Raikow found **carbon dioxide** converts magnesium hydroxide into an acid carbonate. C. J. B. Karsten found that molten **sodium chloride** is not decomposed by magnesia. According to R. E. Hughes, dry **hydrogen sulphide** has not an appreciable action on dried magnesia between 15° and 40°, but in presence of moisture, the gas is absorbed; O. Schumann noted the formation of magnesium sulphide when hydrogen sulphide is passed over heated magnesia. E. Frémy observed that red-hot magnesia is converted into the sulphide by the vapour of **carbon disulphide**. K. Birnbaum and C. Wittich found that **sulphur dioxide** is absorbed by magnesia at 360°, but so slowly that three months are needed for the completion of the reaction. W. T. Smith and R. B. Parkhurst studied the absorption of sulphur dioxide by milk of magnesia. V. Lenher found magnesia dissolves in a soln. of **selenium oxychloride**. When magnesia is heated in a stream of **phosphorus pentachloride**, A. Daubrée noted the formation of crystals of normal magnesium phosphate. M. Berthelot and G. André found magnesia drives ammonia with difficulty from, even boiling, soln. of **ammonium salts**—thus ammonium magnesium phosphate is but very slowly decomposed when boiled with magnesium hydroxide suspended in water. The reduction of magnesia by **carbon** has been discussed in connection with the preparation of magnesium. E. Tiede and E. Birnbrauer said that magnesia is not reduced. O. P. Watts found magnesium oxide is more effectively reduced by certain **carbides** than by carbon alone. The carbides of iron, nickel, and chromium are very active, but those of copper and tin have scarcely any action on the reduction of magnesium oxide. W. G. Palmer found magnesia admixed with cupric oxide to act catalytically on the dehydrogenation of ethyl alcohol. **Siloxicon** and **carborundum** accelerate the reduction. H. Davy studied the action of the **alkali metals** on heated magnesia—*vide* magnesium. F. E. Weston and H. R. Ellis found that magnesia is reduced by **calcium**, but nitride is simultaneously formed. According to H. N. Morse and J. White, when a mixture of magnesia and **magnesium** is heated to redness in an evacuated tube, the magnesium oxide is transported to the cooler part of the tube. The phenomenon is not due to the volatility of the oxide, but is thought to be due to the free metal attracting the oxygen and causing a dissociation of the oxide, which reforms in the cooler part of the tube where the temp. is lower—*vide* zinc and cadmium oxides. C. Matignon argues that every system of liquid or solid bodies which is capable of giving rise to a system furnishing volatile substances, will undergo reaction in that sense at a convenient temp., and the reduction of magnesia by **aluminium**: $2\text{Al} + 3\text{MgO} = 3\text{Mg} + \text{Al}_2\text{O}_3$, is possible because magnesium is volatile at a comparatively low temp. F. E. Weston and H. R. Ellis stated that magnesia is not reduced by aluminium. R. Fink found that when magnesium hydroxide is added to soln. of manganese, iron, or nickel sulphate, basic salts of these metals are precipitated. S. Meunier found that molten potassium hydroxide dissolves half its weight of magnesia, and the molten mixture absorbs oxygen from the air. L. B. Guyton de Morveau heated mixtures of magnesia with **baryta** and with **lime**, but obtained no special results. E. S. Shepherd and co-workers found that the components of fused mixtures of lime and magnesia crystallize out side by side; they furnish a simple eutectic mixture with no evidence of combination; J. B. Ferguson and H. E. Merwin estimated a eutectic at about 2300° and about 32 per cent. MgO. According to J. J. Berzelius, when moistened with **cobalt nitrate**, and strongly ignited before the blowpipe, it takes a fine rose colour; and J. A. Hedvall noted the formation of mixed crystals of calcium and magnesium oxides.

P. Butini, H. Davy, etc., noted the inertness towards **water** of magnesia calcined at a high temp., and H. Rose stated that magnesia prepared by calcining *magnesia alba* does not become warm when mixed with water, while magnesia prepared by calcining trihydrated magnesium carbonate to 300°, becomes hot when mixed with water. The properties of magnesia calcined at high and at low temp. are therefore in marked contrast. As shown by A. Ditte, and W. C. Anderson,¹² the low temp. and low sp. gr. form readily absorbs gases, and moisture; it is readily and quickly dissolved by mineral acids; and it reacts quickly with water. The high temp., high sp. gr. form of magnesia is very resistant to these influences, and it remains practically unacted upon by water, even after the lapse of a considerable time. H. M. Goodwin and R. D. Mailey have stated that fused magnesium oxide possesses in a remarkable degree the ability to withstand the action of many **neutral salts** at high temp., and is therefore well adapted for use as vessels and apparatus for containing such salts when subjected to high temp. Silver, sodium, and potassium nitrates; sodium and potassium chlorides, bromides, and sulphates; zinc chloride; and barium nitrate showed no action on a polished sample of fused oxide when the latter was heated for an hour or more in the fused salt. Barium chloride had a very slight action; while **sodium carbonate, potassium carbonate, potassium hydroxide, and cryolite** attacked the fused oxide energetically. Dil. **nitric, hydrochloric, or sulphuric acid** slowly attacks the fused oxide in the cold; the conc. acids are less active than the dil. acids.

In addition to the manufacture from calcined magnesite of refractory firebricks for basic steel furnaces, the Königlichen Porzellan-manufaktur, Berlin, make various chemical apparatus—tubes, dishes, crucibles, etc.—from fused magnesia. According to K. Arndt, they can be heated in the blast flame without cracking, but, according to E. Wedekind, care is necessary on cooling. J. W. Mellor and F. Austin noted that fused magnesia does not crack like fused quartz does during its devitrification. E. Wedekind says fused magnesia undergoes no shrinkage or electrolysis when heated in the electric furnace at 1750°. In 1806, J. L. Proust mentioned the use of magnesia as a refractory in furnace building; and the use of magnesia in making pottery.

H. St. C. Deville, H. Schwarz, and F. Knapp noted that magnesium oxide prepared by heating magnesium chloride or nitrate to redness has **hydraulic properties** in that when mixed with a limited quantity of water, it sets rigid like portland cement, and the product is hard enough to scratch marble. On the other hand, magnesia, prepared by calcination for 12 hrs. at a white heat, no longer sets with water, or, if it does, the setting is very slow. A. Ditte also made observations: Magnesia prepared by calcining the nitrate at 350°, when fashioned into rods and spheres with water, remains soft and friable when under water 8 months; that calcined at 440°, hardens under water and in 2 months is like polished marble; that calcined at 560°, also is very hard after standing 2 months under water; while that calcined at 1200° does not harden under water. According to W. C. Anderson, magnesium oxide prepared by gently heating the native carbonate reacts quickly with water, and, when in presence of a limited amount of **water**, sets to a firm mass. The product obtained by heating similarly the artificial carbonates does not set, although it also appears to slake rapidly with water, but if these carbonates be treated with nitric acid and the resulting nitrate ignited gently, the oxide left will set similarly to that obtained from the native carbonate by heat.

Magnesia gradually absorbs moisture and carbon dioxide from the atm. E. de M. Campbell¹³ has measured the **rate of hydration** of magnesium oxide burned at different temp., and selections from his measurements are shown graphically and diagrammatically in Fig. 8. The hydration of magnesium oxide burned between 600° and 800° is practically complete in three days; and a change in the constitution of magnesium oxide sets in between 1000° and 1100°, resulting in a marked decrease in the rate of hydration, and this change becomes more and more marked with rise of burning temp., until, at 1450°, or nearly the temp. employed in burning portland cement, the magnesium oxide combines with

only 61.4 per cent. of the water required for complete hydration. C. Edwards and A. Rigby have measured the rates of hydration of dolomite calcined at different temp., and then exposed to atm. of different degrees of humidity, from which it appears that the lime hydrates faster than the magnesia, and that the higher the temp. of calcination up to about 1150° , the faster the rate of hydration; beyond that temp., the higher the temp. of calcination, the slower the rate of hydration. The subject has also been studied by A. M. Sen, and N. Parravano and C. Mazzetti. The latter found that H. le Chatelier's statement that magnesium oxide undergoes a transformation at about 1600° , and E. de M. Campbell's that it changes at about 1100° , are incorrect. The change occurs at 800° , but very slowly. The presence of impurities in the magnesite modify the transformation—e.g. iron oxides accelerate the change. J. W. Mellor showed that there is no definite transformation temp., but that the change proceeds more quickly the higher the temp. of calcination, and each variety of native magnesite has its own specific rate of transformation. The change is possibly a conversion from amorphous to crystalline periclase.

FIG. 8.—Rates of Hydration of Magnesium Oxide Calcined at different Temperatures.

The various determinations of the **solubility** of magnesium oxide or rather hydroxide in water are discordant. Reducing the data by the different observers to milligrams of magnesium hydroxide, $\text{Mg}(\text{OH})_2$, per litre, J. Dalton¹⁴ gave 62.5 in cold water; R. Kirwan, 126.5 in cold water; O. Henry, 172.4 at 15° ; A. Fyfe, 194.5 at ordinary temp., and 27.8 at 100° ; R. Fresenius, 27.8 in either cold or boiling water; A. Bineau, 5 to 10 in cold water; F. Kohlrausch and F. Rose, 9 at 18° ; A. Dupré and M. Bialas, 8 at 18° ; and G. C. Whipple and A. Mayer, 12 at 22° . The wide variations in the results are due to the magnitude of the sources of error in contrast with the magnitude of the constant being measured. These errors are: (i) The solvent action of carbon dioxide dissolved by the water from the air; (ii) the action of water on the glass containing vessels whereby bases are dissolved, and when the solubility is estimated from the alkalinity of the soln., the dissolved alkali introduces a large error; (iii) the presence of such impurities as lime in the magnesia would introduce a large error when lime plus magnesia is regarded as magnesia; and (iv) the uncertainty involved in the assumption that equilibrium is attained since the rates of dissolution of magnesia, prepared in different ways, are very different. The best representative value of the modern determinations of the solubility of magnesia in water is 10 mgrms. of magnesium hydroxide per litre of water at 20° . W. C. Anderson showed that a given oxide, calcined at different temp., dissolves in water at different rates, the rate of soln. being diminished as the temp. of preparation is increased; on the other hand, the extent of this diminution is not the same for oxides obtained from different sources. It is greatest in the case of the oxide obtained from heavy carbonate, less marked in the product from crystal carbonate, and scarcely appreciable in that from light carbonate. The aq. soln. of magnesia is not caustic, but it has an alkaline reaction, changing red litmus blue, etc.

According to H. Precht, a litre of a 2*N*-soln. of potassium hydroxide dissolves 16.13 mgrms. of magnesium hydroxide. R. Warington showed that the solubility of magnesium hydroxide is augmented by ammonium salts, even in the presence of free ammonia. From experiments on the equilibrium: $\text{Mg}(\text{OH})_2 + 2\text{NH}_4\text{Cl} \rightleftharpoons \text{MgCl}_2 + 2\text{NH}_4\text{OH}$, at 10° , J. M. Lovén calculated that the solubility of magnesium hydroxide is 3.5×10^{-4} mols per litre; and at 29° , W. Herz and G. Muhs calculated

2.3×10^{-4} mols per litre. Like J. M. Lovén, F. P. Treadwell concludes that the non-precipitation of magnesium hydroxide by ammonia in the presence of ammonium salts is not due to the formation of a complex salt, but solely to the retardation of the dissociation of the ammonium hydroxide by the ammonium chloride according to the law of mass action. W. Herz and G. Muhs give for the solubility of magnesia in ammonium salt soln. at 29° , when the conc. are expressed in grams per litre,

	NH ₄ Cl					NH ₄ NO ₃	
Ammonium salt . . .	4.13	5.67	9.21	13.39	20.86	6.00	14.69
Magnesium hydroxide .	1.43	1.86	2.00	3.15	4.55	1.45	2.43

When warm soln. of ammonium salts are heated with magnesia, ammonia is evolved. R. Warrington found *sodium and potassium salts* act similarly in their solvent action on magnesia, but to a less degree. C. J. B. Karsten stated that magnesium hydroxide is insoluble in conc. aq. soln. of many salts—*e.g.* sodium chloride, sulphate or nitrate, barium nitrate and chloride, and potassium nitrate. O. Henry reported that the presence of *calcium hydroxide, calcium sulphate, or potassium sulphate* does not interfere with the solvent action of water on magnesia. In general, however, F. K. Cameron and J. M. Bell say that *the solubility of magnesia in water is augmented by various salts, including magnesium salts, but is depressed by the alkali hydroxides*. E. Maigret found the presence of the free base, sodium hydroxide, lowers the solubility of magnesia in a soln. of sodium chloride. Expressing conc. in grams per litre,

	0.8 grm. NaOH			4.0 grms. NaOH		
Sodium chloride . . .	125	140	160	125	140	160 grms.
Magnesium hydroxide .	0.07	0.045	nil	0.03	nil	nil

G. Fleury found the solubility of magnesia in water is increased when *glucose* is present; although C. Bernard and L. Ehrmann ignored this in using sugar soln. to remove lime from magnesia. C. Neuberg and B. Rewald¹⁵ found that magnesia slowly dissolves when shaken for a long time with *methyl alcohol*, forming a typical **magnesia alcosol** which contains in a litre an amount of magnesia corresponding with 4.5 per cent. $\text{Mg}_2\text{P}_2\text{O}_7$, *i.e.* 1.63 per cent. MgO .

Magnesium hydroxide, $\text{Mg}(\text{OH})_2$.—The mineral *brucite* was discovered in 1814 by A. Bruce¹⁶ at Hoboken (New Jersey); it was called *talc-hydrate* by C. C. von Leonhard; *magnésie hydratée* by R. J. Haüy, and F. S. Beudant applied the term *brucite* in 1824. The mineral is found with magnesite and dolomite in serpentine as a result of the decomposition of magnesian silicates. J. Pierce, and T. Nuttall described a fibrous or amianthoidal form of magnesia which was designated *nemalite* or *nematolite*—from *νήμα*, a fibre. J. D. Whitney, and C. F. Rammelsberg proved its chemical identity with brucite. Magnesium hydroxide is formed during the hydration of magnesium oxide. G. O. Rees¹⁷ stated that magnesia is converted into the hydroxide by moistening it with water, and drying the mass on a water-bath. Colloidal and a readily soluble form of the hydroxide is produced by the action of water or steam at 150° on magnesia. The **colloidal magnesium hydroxide** is readily obtained by adding an excess of potassium or sodium hydroxide to a soln. of a magnesium salt. As remarked by P. Grouvelle,¹⁸ and R. F. Marchand and T. Scheerer, it is difficult to wash the precipitate free from alkalis. H. E. Patten found that magnesium hydroxide does not carry into precipitation with it either chlorine or sulphur trioxide; and at 20° , more than the theoretical amount of potassium hydroxide is required for complete precipitation. The washed and dried hydroxide is a white powder, or, when dried at 100° , is a translucent, coherent, soft brittle mass—presumably in the colloidal state. A. de Schulten prepared crystallized magnesium hydroxide as follows:

12 grms. of magnesium chloride, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 340 grms. of potassium hydroxide, and 60 c.c. of water, are heated at 212° – 220° until the magnesium hydroxide completely dissolves. If the proportion of potash is larger, a lower temp. is sufficient. The liquid is allowed to

cool, and the solid residue treated with water to remove the alkali. The magnesium hydroxide is left undissolved in the form of small, distinct crystals of sp. gr. 2.36 at 15°; these dissolve easily in acids and in warm conc. soln. of ammonium chloride. If soda is used instead of potash, the magnesium hydroxide does not dissolve, but the precipitate rapidly becomes crystalline.

G. Friedel also made crystals of the hydroxide by the action of soda lye on magnesia at 400°, and he considers that this explains the formation of crystals of brucite in boiler deposits, observed by G. A. Kenngott, A. Weisbach, and O. Luedecke.

According to F. Hessenberg,¹⁹ the **crystals** of brucite are trigonal, with $a:c=1:1.52078$, and $\alpha=81^\circ 12'$. R. Hermann described some crystals of magnesium hydroxide from Texas, Pa., as monoclinic, and called the mineral *texalite*, which would make magnesium hydroxide dimorphous, but this is not yet established because the crystals behave optically like brucite. G. Aminoff calculated from the **X-radiograms** that the elementary parallelepiped has $a=3.13$ A., and $c=4.75$ A. The **specific gravity** of artificial crystals was found by A. de Schulten to be 2.36 at 15°. For brucite, R. Hermann gave 2.36; W. Beck, 2.376; A. A. Lösch, 2.388; F. R. Mallet, 2.454 at 15°; M. F. Heddle, 2.336–2.37; L. Peruzzi, 2.385 at 17°; and V. von Zepharovich, 2.39. The **hardness** is 2 on Mohs' scale. O. Mügge has studied the **percussion figures** of brucite.

According to J. M. van Bemmelen,²⁰ the hydroxide passes into the oxide at a temp. below a red heat; it does not lose its combined water in a dry atm. at 350°, but it does so between 350° and dull redness. The hydroxide dried over sulphuric acid without heating, absorbs about 1.6 mols of water when exposed to moist air, but it loses this property if previously heated to 200°, owing to its conversion from the colloidal to the crystalline state. Magnesia obtained at a dull red heat, again takes up $1\frac{1}{2}$ mols of water and one mol of this is retained as water of constitution, $Mg(OH)_2$; if the magnesia has been obtained by ignition at a still higher temp., it is only partially converted into hydroxide in a moist atm., and if calcined 20 hrs. at this temp., it no longer takes up water of constitution. J. Johnston found the **dissociation pressure** of magnesium hydroxide to be:

	35°	53°	74°	100°	147°	c. 160°
Vap. press.	9.2	31.5	92	234	526	760 mm.

At 25°, the press. is 2.3×10^{-3} atm., and the dissociation temp. is approximately 160°.

A. des Cloiseaux²¹ found brucite had a strong positive **double refraction**. The plate-like crystals of brucite resemble those of gypsum and talc in softness, foliated structure, cleavage and lustre, but gypsum is biaxial, and talc has negative double refraction. M. Bauer gave for the **index of refraction** with red light for the ordinary ray $\omega=1.559$, and for the extraordinary ray $\epsilon=1.5795$. L. Peruzzi found $\omega=1.562$, and $\epsilon=1.5827$. M. Bauer, R. Brauns, and H. Rosenbusch have studied the modification in the optical properties of the crystals by strain. U. Panichi found that no change in the optical properties occurred when the crystals were cooled to -190° . W. W. Coblenz,²² and J. Königsberger studied the **infra-red absorption spectrum** of brucite and noted that gypsum shows an absorption spectrum which is a composite of the bands of water and of anhydrite, while that of brucite is different, thus distinguishing between the water of crystallization of gypsum from the water of constitution of brucite. There is a large band near 2.5μ which with higher dispersion is resolved into three bands with maxima at 2.5μ , 2.7μ , and 3μ ; beyond this region there are no marked bands, while beyond 12μ there is complete opacity. There are depressions in the transmission curve for 5μ , 7μ , 7.7μ , 8.2μ , 9.7μ , and 10.8μ , but as a whole the curve is conspicuous for the absence of sharp absorption bands.

F. Beijerinck²³ found that the **electrical conductivity** of brucite is nil. W. Hankel found that the crystals exhibit **pyroelectricity**, for, on cooling, the two ends of the principal axis and the adjacent surfaces are electrically negative, while

the corners of the base and the neighbouring surfaces are electrically positive. J. C. Bose studied the absorption of electrical waves by nemalite.

Magnesium peroxide.—C. Weltzien's experiment²⁴ on the action of hydrogen peroxide on magnesium has already been indicated. R. Haas treated a soln. of a magnesium salt, containing 3 per cent. hydrogen peroxide, with aq. ammonia, and obtained a precipitate which contained some active oxygen, and appeared to have the characteristics of a peroxide. R. Wagnitz patented a preparation made by mixing 50 parts of magnesium hydroxide or hydrocarbonate, moistened with about 5 parts of water, with 10 to 12 parts of sodium peroxide; other modes of mixing were also employed. Undue heating of the mixture should be avoided. F. J. Homeyer also added sodium or barium peroxide to the soln. of a magnesium salt and obtained a product estimated to contain 30 per cent. magnesium dioxide, MgO_2 . A. Krause also patented analogous mixtures. O. Ruff and E. Geisel attempted to prepare pure magnesium peroxide by the addition of pure sodium hydroxide to magnesium sulphate soln. in the presence of hydrogen peroxide. Even when a large excess of the latter is used, the precipitate in the moist state has the ratio $\text{MgO} : \text{O} = 1 : 0.67$. Drying the precipitate reduces the proportion of peroxide oxygen, and a product is obtained which has the composition $\text{MgO} \cdot \text{MgO}_2$, aq. The dried product readily loses oxygen at 25° or 37° , and at atm. press., but even after 22 days the ratio $\text{MgO} : \text{O}$ was $1 : 0.39$, and the ratio appears to remain constant at $1 : 0.35$, corresponding roughly with the formula $\text{MgO}_2 \cdot 3\text{MgO}$, aq. The decomposition is more rapid in the presence of water.

E. Merck agitated dried magnesium oxide with anhydrous hydrogen peroxide; the anhydrous solid is easily separated from the water formed in the reaction, and does not require washing. A repetition of the treatment furnishes a peroxide of high degree of purity. F. Hinz used an electrolytic process for preparing magnesium peroxide. The anode compartment of an electrolytic cell is supplied with an aq. (about 20 per cent.) soln. of magnesium or zinc chloride, whilst the cathode compartment contains magnesium or zinc chloride soln. to which hydrogen peroxide has been added; the anode is of platinum or carbon, and the cathode platinum. An e.m.f. of 6 or 7 volts is used in preparing magnesium peroxide, and 2.5 to 3 volts for zinc peroxide. Any free acid formed in the cathode compartment is neutralized by the addition of magnesium or zinc oxide or hydroxide. The reaction presumably progresses $\text{Mg} + \text{H}_2\text{O}_2 + 2\text{H}_2\text{O} \rightarrow \text{H}_2 + \text{Mg}(\text{OH})_4$.

The peroxides of the alkaline earths, zinc, and magnesium have attracted some attention on account of their chemical and physiological properties and their use as antiseptics. Magnesium peroxide is a white powder which may be magnesium hydroperoxide, $\text{Mg}(\text{OH})_4$; and it usually contains some magnesium hydroxide, and water. R. von Foregger and H. Philipp say "preparations containing certain amounts of available oxygen are more stable than other preparations containing more or less than these." Thus, a product containing 9.2 per cent. of available oxygen seems to be stable, whilst if a product contains less than this it gradually loses its available oxygen, till it reaches 8 per cent. available oxygen, when it again remains stable; and stable products occur containing 6.85 to 6.9 per cent., and also 4.3 per cent. oxygen. The less available oxygen the product contains the more stable it is under atm. conditions. The ordinary product contains about 8 per cent. oxygen and has a sp. gr. of 0.615. Magnesium peroxide has the solubility of 1 part in 14,550 parts of water at 20°C . Suspended in water it loses its available oxygen quicker than zinc peroxide, and slower than calcium or strontium peroxides, but it loses its available oxygen quicker in moist atm. than the other peroxides, as it is apparently more subject to the influence of carbon dioxide. In a dry atm. it is, however, comparatively stable, and can be heated to 160°C . without any loss. It reacts like these other peroxides with acids and certain organic matters.

§ 7. Magnesium Fluoride

The mineral *sellaïte* is a native magnesium fluoride, MgF_2 , which G. Strüver¹ found at Moutiers in France. It forms colourless or white tetragonal crystals of sp. gr. 2·9–3·2; and hardness 5–6. A. and E. Scacchi found some crystals in the lava of the Vesuvian eruption of 1872 which they called *belonesite* or *belonite*, and which were shown by F. Zambonini to be identical with G. Strüver's *sellaïte*.

J. L. Gay Lussac and L. J. Thénard² dissolved magnesium oxide in hydrofluoric acid. J. J. Berzelius prepared magnesium fluoride by treating magnesium carbonate with hydrofluoric acid, or by precipitation from a soln. of magnesium sulphate by potassium fluoride. F. Röder obtained it by melting together 5 parts of magnesium chloride, 4 parts each of sodium fluoride and chloride; on cooling, long needle-like crystals of magnesium fluoride are obtained. H. Moissan made magnesium fluoride by burning the powdered metal in fluorine gas—the combustion proceeds *avec beaucoup d'éclat*; A. Feldmann heated magnesium chloride with calcium fluoride, and digested the product with water acidulated with hydrochloric acid. The product obtained by dissolving the oxide or carbonate in hydrofluoric acid, or by passing gaseous hydrogen fluoride over magnesium oxide, is an amorphous powder which is not converted into crystals either by heating it with dil. hydrochloric acid to 250°, or by the evaporation of its soln. in nitric acid; but, according to A. Cossa, it may be crystallized by cooling the fused fluoride, or by melting it with alkali chlorides—these crystals resemble *sellaïte*. According to A. Sella, the crystals are tetragonal with the axial ratio $a : c = 1 : 0\cdot6596$.

The sp. gr. of artificial crystals of magnesium fluoride, determined by A. Cossa,³ is 2·857 (12°), and for the natural crystals the sp. gr. vary from G. Strüver's 2·962 to 3·153 (16°); H. G. F. Schröder gives 2·472 as the sp. gr. of the precipitated and calcined powder. The hardness of *sellaïte* is about the same as apatite, 6. Magnesium fluoride, said E. Beck, has the m.p. 1396°, and it forms a eutectic with 48 per cent. of calcium fluoride, melting at 945°. This eutectic appears to form mixed crystals with up to 17 per cent. of barium fluoride. There is a ternary eutectic with 15 per cent. magnesium fluoride, 15 per cent. calcium fluoride, and 70 per cent. barium fluoride, which melts at 790°; and by adding magnesium oxide, the ternary eutectic is lowered to 764°. According to A. Guntz, the heat of formation (Mg , $\text{F}_{2\text{gas}}$) = 67·4 Cals.; and the thermal values of the reactions $\text{MgSO}_4 + 2\text{KF} = \text{MgF}_{2\text{solid}} + \text{K}_2\text{SO}_{4\text{soln.}} - 0\cdot87$ Cal. at 10° when an eq. of the salts are present in two litres of water; $\text{MgO}_{\text{ppd.}} + 2\text{HF}_{\text{soln.}} = \text{MgF}_{2\text{ppd.}} + \text{H}_2\text{O} + 15\cdot2$ Cals. with an eq. of the acid in two litres of water; and $\text{Mg}(\text{OH})_{2\text{ppd.}} + 2\text{HF}_{\text{gas}} = \text{MgF}_2 + 2\text{H}_2\text{O}_{\text{solid}} + 28\cdot4$ Cals.; E. Petersen gives $\text{Mg}(\text{OH})_{2\text{aq.}} + 2\text{HF}_{\text{aq.}} = 30\cdot12$ Cals. *Sellaïte* has a feeble refracting power; the double refraction is positive. E. Mallard, A. Sella, and F. Zambonini found for sodium light indices of refraction between $\omega = 1\cdot3775$ and $1\cdot379$; and $\epsilon = 1\cdot3889$ and $1\cdot3897$. Warm crystals of *sellaïte* show a faint violet luminescence with cleavage, a property which is lost by calcination; A. Cossa also found that the natural or artificial crystals give a violet fluorescence when heated after exposure to the arc light. S. Datta studied the three groups of spectral bands of magnesium fluoride.

According to F. Kohlrausch, a litre of water at 18° dissolves 0·076 grm. of MgF_2 by the conductivity method—the specific conductivity of the sat. soln. being 0·000224 at 18°—but the salt is rather more soluble in ammoniacal soln. Magnesium fluoride in many of its properties recalls those of calcium fluoride. J. L. Gay

Lussac and L. J. Thénard found magnesium fluoride is but slightly soluble in acids ; and J. J. Berzelius, that it is insoluble in hydrofluoric acid. A. Cossa showed that it is decomposed by conc. sulphuric acid less easily than calcium fluoride ; and decomposed by fusion with alkali carbonates more easily than calcium fluoride. L. E. Rivot found it to be insoluble in soln. of ammonium or magnesium salts. The amorphous form, however, is more readily attacked than the crystalline variety. H. Schulze said that magnesium fluoride is not decomposed when calcined in oxygen ; A. Tissier, that it is not decomposed by calcium oxide ; A. Cossa, that it forms fusible compounds with the sulphates of the alkaline earths, and that when calcined with beryllium or aluminium sulphate it forms the respective fluoride. W. Weldon once recommended the use of magnesium fluoride in the manufacture of soda ash ; and it has also been tried as an opacifying agent in the manufacture of glass.

A. Tissier,⁴ and M. Netto prepared cubic crystals of **sodium magnesium fluoride**, NaF.MgF_2 , by boiling magnesium hydroxide with an aq. soln. of sodium fluoride : $3\text{NaF} + \text{Mg}(\text{OH})_2 = 2\text{NaOH} + \text{NaF.MgF}_2$. A. Geuther found crystals of the same product in the slag obtained in the preparation of magnesium silicide by fusing magnesium with sodium fluosilicate and chloride. The compound is decomposed by conc. sulphuric acid, and by milk of lime : $\text{Ca}(\text{OH})_2 + 2\text{NaF.MgF}_2 = 2\text{NaOH} + \text{CaF}_2 + 2\text{MgF}_2$. M. Netto also made 2NaF.MgF_2 by fusing hexahydrated magnesium chloride or sulphate with sodium fluoride and chloride.

A. Duboin prepared quadratic prisms of **potassium magnesium fluoride**, KF.MgF_2 by extracting with water the slowly cooled cake obtained by fusing a mixture of an excess of potassium fluoride and magnesium oxide at a red heat. The magnesium slowly dissolves in the fused fluoride. The sp. gr. of the insoluble crystals is 2.8 (0°) ; they are decomposed by sulphuric and hydrochloric acids. If a large proportion of magnesium oxide be used, a hard transparent mass of 2KF.MgF_2 is formed of sp. gr. 2.7 (0°). It is completely decomposed by hydrochloric and sulphuric acids, and slightly decomposed by the prolonged action of boiling water.

§ 8. Magnesium Chloride

Magnesium chloride is widely scattered in nature; it occurs in many mineral waters and in sea-water. The water of the Mediterranean is said to contain a rather larger proportion than the Atlantic Ocean, and *le sel*, which is extracted from the salt gardens of the Mediterranean, has a more bitter taste than *le sel* obtained from those which are concentrated from the waters of the Atlantic. In 1825, T. Monticelli and N. Covelli¹ found *magnesia muriata* in the fumaroles and volcanic vents of Vesuvius; in 1832, L. Pilla noted its occurrence along with sodium chloride in the crater crusts; and A. Scacchi found it in the eruptions in 1855 and 1872, and he proposed the name *chloromagnesite*, and assigned to it the formula $\text{MgCl}_2 \cdot x\text{H}_2\text{O}$. F. Zambonini considers the magnesium chloride in these deposits is united as a double salt with the alkali chloride. The mineral *bischofite*, hexahydrated magnesium chloride, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, found in the Stassfurt deposits, was named by C. Ochsensius in honour of G. Bischof. It occurs in the carnallite, kieserite, and salt clay regions, and it is supposed to be a secondary constituent formed by the action of water on carnallite. Magnesium chloride also occurs as *carnallite*, $\text{MgCl}_2 \cdot \text{KCl} \cdot 6\text{H}_2\text{O}$, or $\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$; and as *tachyhydrite*, *tachhydrite*, or *tachydrite*, $\text{MgCl}_2 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$, or $(\text{Ca}, \text{Mg})\text{Cl}_2 \cdot 6\text{H}_2\text{O}$, in the Stassfurt deposits.

J. L. Gay Lussac and L. J. Thénard² made anhydrous magnesium chloride by leading chlorine gas over red-hot magnesium oxide. The oxygen simultaneously evolved was attributed to the decomposition of chlorine which they called oxy-muriatic acid—according to R. Weber, the reaction proceeds without incandescence, and requires a much higher temp. than is needed for the analogous reaction with lime or baryta. P. S. Curie also made the chloride by passing hydrogen chloride over magnesium sulphide. A. A. B. Bussy and J. J. Berzelius made it by passing chlorine over a red-hot mixture of magnesia and carbon in a porcelain tube—the magnesium chloride collected at the bottom of the tube without sublimation. The De Nordske Saltverker has a modification of this process for working on a large scale. J. von Liebig, R. Bunsen, and J. A. Wanklyn and E. T. Chapman obtained the anhydrous chloride by burning the metal in chlorine gas. According to R. Cowper, if the gas is quite dry magnesium is not attacked by chlorine. J. W. Döbereiner and R. Bunsen obtained the anhydrous chloride by calcining dry ammonium magnesium chloride.

R. Bunsen added sufficient ammonium chloride to a soln. of magnesium carbonate in hydrochloric acid, to prevent the precipitation of magnesium hydroxide when aqua ammonia is added until the soln. is slightly alkaline. Any silica, etc., which separates is filtered off, and the clear liquid is neutralized with hydrochloric acid and evaporated to dryness. The double ammonium and magnesium chloride so obtained is melted at about 460° in a Hessian crucible, in the bottom of which is placed a smaller platinum dish. When the ammonium chloride is all expelled, the magnesium chloride collects in the platinum dish.

According to H. St. C. Deville and H. Caron, and E. Sonstadt, the magnesium chloride so prepared frequently contains nitrogen, and, according to J. B. A. Dumas, magnesium oxide. In a modification of the process, a mixture of magnesium oxide and ammonium chloride is heated, and more ammonium chloride added from time to time. M. M. T. K. Kaisha, and I. Namari and Y. Hiraoka added ammonium chloride and the oxide, hydroxide, carbonate, or oxychloride of magnesium to a fused halide of a more electropositive metal. The product was considered suitable for electrolysis for magnesium.

W. Heap and E. Newbery made anhydrous magnesium chloride by treating the oxide or a salt with a weak acid—carbonate or oxalate—with carbonyl chloride at 500° – 600° . A mixture of carbon monoxide and chlorine passed over animal charcoal will serve the same purpose. H. J. Bull used carbon tetrachloride or carbonyl chloride with magnesia, or magnesite; if dolomite is used, a mixture of calcium and magnesium chlorides is obtained which may be used in electrolysis.

V. M. Goldschmidt chlorinated magnesia in the presence of sulphur or sulphur chlorides free from oxygen, and at 200°–500° found that the reaction went according to the equation: $2\text{MgO} + 2\text{Cl}_2 + \text{S} = \text{SO}_2 + 2\text{MgCl}_2$.

T. W. Richards and H. G. Parker heated the dried ammonium magnesium chloride in a stream of dry hydrogen chloride and obtained magnesium chloride of a high degree of purity. The magnesium chloride soln. used in the preparation of the double salt was purified in the following manner:

About 500 grms. of magnesium chloride were sat. with hydrogen sulphide, a small amount of ammonia was added, and the whole was allowed to stand in a warm place for several days. To the supernatant liquid after decantation a small quantity of very pure ammonium oxalate was added. The magnesium chloride thus almost wholly freed from calcium was again decanted; and after more ammonium oxalate had been added, the whole was allowed to stand, and the clear liquid was yet once more decanted. The soln. was then evaporated to dryness, and the resulting cake dried in an oven and ignited in a platinum dish. The mixture of magnesium oxide and oxychloride thus formed was washed with the aid of a filter pump for about sixty hours. At the end of this time, although the wash water contained no sodium, the insoluble precipitate was not free from that metal. The precipitate was therefore dissolved in hydrochloric acid, previously distilled in platinum for the purpose, and the soln. was filtered. In order to eliminate the sodium, a portion of the magnesium was precipitated by passing into the soln. a current of ammonia gas. The precipitate formed by this very wasteful process was washed for several days, at the end of which time it was found to be free from any appreciable traces of sodium and potassium, when tested with the spectroscope. The precipitate was then dissolved in hydrochloric acid.

In the laboratory a soln. of magnesium chloride is made by dissolving magnesium oxide or carbonate in hydrochloric acid. It can also be made by a process analogous to that employed by A. J. Balard for separating Glauber's salt from sea-water, namely, by cooling a conc. soln. of magnesium sulphate and sodium chloride whereby sodium sulphate crystallizes out, and magnesium chloride remains in soln. According to L. Michels, the hydrated salt is made from the mother liquor remaining after extracting potassium chloride from the Stassfurt salts; this is evaporated until its sp. gr. is about 1.375, and then allowed to cool and crystallize. The syrupy yellowish-brown mother liquid contains bromides. The crystals, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, are melted (about 400°), and they are at the same time partially dehydrated and partly oxidized to an oxychloride. The mixture forms some of the magnesium chloride of commerce. Magnesium chloride could be obtained as a by-product in one of W. Weldon's processes for chlorine; and in E. Solvay's ammonio-soda process if magnesium oxide be used to decompose the ammonium chloride. K. S. Boynton and co-workers discuss the recovery of magnesium chloride from sea-water, where it is obtained as a by-product in the extraction of salt. H. H. Dow and E. O. Barstow proposed to remove calcium chloride from magnesium chloride brine by precipitation as calcium sulphate. C. Clerc and A. Nihoul added calcined dolomite in powder to a soln. of magnesium chloride, and found magnesia to be precipitated and calcium chloride to pass into soln.

The hydrated salt cannot be dehydrated without a loss of hydrogen chloride by simple heating. According to R. Brandes, the loss of hydrogen chloride begins at 106°, and, according to H. Grimshaw, at 117° or even lower temp. H. Hof detected the formation of hydrogen chloride at 157° when soln. of magnesium chloride are evaporated under conditions where the superheating of any part of the soln. is prevented. F. P. Dunnington and F. W. Smither say that all but one mol of the water of crystallization can be expelled at 38° without decomposition, and that the principal loss of hydrogen chloride occurs during the expulsion of the residual water. E. Solvay has patented a process in which an approximation is made by heating the hexahydrated salt to 120° until 80 per cent. of the water is expelled; the residue is then much more resistant, and it can be heated to a higher temp. without much loss as hydrogen chloride; or the hexahydrated salt can be heated until about 50 per cent. of the water is expelled, and the molten salt then broken into small fragments and heated between 300° and 400° in a stream of dry air. In the

Salzbergwerk Neu-Stassfurt's process, it is claimed that the hexahydrated salt can be dehydrated without much loss of hydrogen chloride by heating it to about 175° in vacuo. E. Sonstadt and W. Hempel recommended dehydrating the hexahydrated salt in a stream of dry hydrogen chloride. H. J. Bull used a stream of carbon tetrachloride or carbonyl chloride at 500° – 600° . H. H. Dow has described a process for dehydrating this salt. If magnesium oxide is once formed, J. B. A. Dumas found it to be difficult to chlorinate subsequently the oxide. F. A. Gooch and F. M. McClenahan say that the passage of hydrogen chloride has no influence on the speed of dehydration of the first third of the water which occurs at 100° , but that it retards the dehydration between 100° and 130° ; and accelerates it above 130° . The hydrolytic dissociation of this salt is not very marked below 200° in air or in hydrogen chloride. F. A. Gooch and F. M. McClenahan found that one-third of the combined water can be expelled from the hexahydrated chloride easily without hydrolysis, but the remaining two-thirds can be driven off only when accompanied by hydrogen chloride, and they explain this by assuming that two-thirds of the combined water is more intimately associated in the mol. complex than the remaining third. They illustrate this graphically :

Compare this with the behaviour of hydrated barium and aluminium chlorides.

J. L. Gay Lussac and L. J. Thénard³ described anhydrous magnesium chloride as forming a white transparent mass of large lustrous **crystals** with a sharp bitter taste. L. Playfair and J. P. Joule found the sp. gr. to be 2.177. H. St. C. Deville and H. Caron say that the salt may be distilled in a current of hydrogen, forming a distillate resembling butter, which forms a mass of crystalline plates on cooling. E. E. Somermeier found the heat of dissolution of a gram-atom of magnesium in $\text{HCl}+19.15\text{H}_2\text{O}$ to be 111.40 Cals. The **melting point** is 708° , according to T. Carnelley, and the f.p. 711° , according to O. Menge. J. Thomsen gives the **heat of formation**, (Mg, Cl_2) , 151.01 Cals.; $(\text{Mg}, \text{Cl}_2, \text{aq.})$, 186.93 Cals.; $(\text{MgCl}_2, \text{aq.})$, 35.92 Cals.; $(\text{Mg}, \text{Cl}_2, 6\text{aq.})$, 133.98 Cals.; $(\text{MgCl}_2, 6\text{aq.})$, 32.97 Cals.; $\text{Mg}(\text{OH})_{2\text{aq.}}+2\text{HCl}_{\text{aq.}}=27.69$ Cals. G. F. Hüttig gave 2.325 at $25^{\circ}/4^{\circ}$ for the **specific gravity** of anhydrous magnesium chloride, 2.316 for that of the unmelted and porous salt; and, assuming the sp. gr. is 2.320, W. Biltz gives the mol. vol. 41.05. The **heat of solution** of $\text{MgCl}_2.6\text{H}_2\text{O}$ in 400 mols. of water is 2.95 Cals., and P. Sabatier gives the ht. of soln. of $\text{MgCl}_2.6\text{H}_2\text{O}$ at 19.6° as 6.4 Cals. M. Berthelot and L. Ilosvay de N. Ilosva give for the heat of soln. of magnesium chloride, MgCl_2 at θ° , $35480+0.0000796(\theta-15^{\circ})$; and for $\text{MgCl}_2.6\text{H}_2\text{O}$, $2800+0.000025(\theta-15^{\circ})$. R. Görgey found for sodium light the **indices of refraction** $\alpha=1.495$; $\beta=1.507$; and $\gamma=1.58$. W. Hampe says that the molten salt is a good conductor of electricity.

According to H. Schulze,⁴ magnesium chloride forms magnesium oxide when calcined in oxygen. The reaction has been discussed in connection with the preparation of chlorine, or of hydrogen chloride. F. Haber and F. Fleischmann represent the equilibrium constant K_p of the reaction: $2\text{MgCl}_2+\text{O}_2\rightleftharpoons 2\text{MgO}+2\text{Cl}_2$, by the expression $\log_{10} K_p=-1950T^{-1}-1.87 \log_{10} T+7.01$, where K_p is equal to $p/p_0^{\frac{1}{2}}$, where p denotes the partial press. of the chlorine, and p_0 that of the oxygen. According to W. Moldenhauer, the following are the values of K_p and the corresponding percentage amounts of oxygen and chlorine by volume calculated from the conc. of oxygen $C_0=100-C$, where C is the conc. of the chlorine; hence $K_p=C/(100-C)^{\frac{1}{2}}$:

	50°	150°	250°	350°	450°	550°	650°	750°
K_p . . .	0.03	0.4	1.9	5.3	10.6	17.4	25.3	35.9
Chlorine . . .	0.3	4.0	17.6	40.8	63.5	79.3	88.0	93.3
Oxygen . . .	99.7	96.0	82.4	59.2	36.5	20.7	12.0	6.7

The equilibrium at the lower temp. is attained very slowly; the values below 350° are computed by extrapolation in the formula; the equilibrium curve is shown in Fig. 9, the dotted curve shows the results obtained after 10 hrs. heating and illustrates the tardiness with which equilibrium is attained at the lower temp. The heats of formation of magnesium chloride is 151 Cals., and of magnesium oxide, 143.3; consequently the thermal value of the reaction: $\text{MgCl}_2 + \text{O} = \text{MgO} + \text{Cl}_2$

FIG. 9.—Equilibrium Conditions in $2\text{MgCl}_2 + \text{O}_2 = 2\text{MgO} + 2\text{Cl}_2$.

FIG. 10.—Equilibrium Conditions in the Reaction: $\text{MgCl}_2 + \text{H}_2\text{O}$.

—7.7 Cals. at constant press. The value computed from J. H. van't Hoff's equation between 550° and 650° is:

$$\log \frac{K_1}{K_2} = \frac{Q}{2} \left(\frac{1}{T_1} - \frac{1}{T_2} \right); \text{ or } \log \frac{25.3}{17.4} = \frac{Q}{2} \left(\frac{1}{923} - \frac{1}{823} \right)$$

or $Q = -5600$ cal. at about 600°, and at room temp., about —7400 cal. J. W. Döbereiner also showed that magnesium chloride is decomposed when heated with potassium chlorate; and by water vapour.

The action of steam on magnesium chloride has been studied by W. Moldenhauer. The composition of the solid residue at different temp. when magnesium chloride is heated with steam is:

		250°	300°	350°	400°	600°
MgCl ₂	.	78.2	72.9	77.7	64.3	41.8
MgO	.	5.1	17.6	15.0	24.3	54.4
H ₂ O	.	16.7	9.5	7.3	11.6	0.8

The composition of the gases in percentages of volume:

		183°	213°	250°	300°	350°	400°	500°	600°	700°
HCl	.	0.8	7.9	21.0	66.5	69.4	62.15	50.2	75.1	90.2
H ₂ O	.	99.2	92.1	79.0	33.5	30.3	37.85	49.8	24.9	9.8

The results are plotted in Fig. 10. W. Moldenhauer attributes the phenomena to changes in the composition, the solid phase being such that the amount of hydrogen chloride in the reaction between steam and magnesium chloride steadily increases up to a maximum between 300° and 350°; between 350° and 505°, magnesium hydroxychloride, Mg(OH)Cl , is formed by a reaction which decreases the proportion of hydrogen chloride in the system; the equilibrium reaction is then represented, $\text{MgCl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{Mg(OH)Cl} + \text{HCl}$; between 500° and 510°, the hydroxychloride, Mg(OH)Cl , decomposes; and above this temp., the equilibrium reaction is: $\text{MgCl}_2 + \text{H}_2\text{O} \rightleftharpoons 2\text{HCl} + \text{MgO}$. The curve between 200° and 350° is uncertain because of the long time required to attain equilibrium. The equilibrium constant K in the reaction: $\text{MgCl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{Mg(OH)Cl} + \text{HCl}$, when $K = [\text{HCl}]/[\text{H}_2\text{O}]$, where the bracketed terms represent concentrations, is $K = 1.64$ at 400°, and $K = 1.01$ at 500°, so that from J. H. van't Hoff's equation, the heat of the reaction between these temp. is 5100 cal. Similarly, the equilibrium constant K' in the reaction $\text{MgCl}_2 + \text{H}_2\text{O}$

$=\text{MgO}+2\text{HCl}$, when $K=[\text{HCl}]^2/[\text{H}_2\text{O}]$ is $K=226.5$ at 600° , and $K=830.2$ at 700° ; and the computed heat of the reaction is -22000 cals. on the imperfect assumption that the sp. ht. of the reacting substances are independent of temp. From the thermochemical data, $\text{MgCl}_2+\text{H}_2\text{O}=\text{MgO}+2\text{HCl}$, $-151000-57000+143300+44000=-20700$ cals. The reaction involving the formation of the intermediate $\text{Mg}(\text{OH})\text{Cl}$ is exothermal, the other reaction at the higher temp. being endothermal.

The **solubility** of magnesium chloride expressed in grams of MgCl_2 per 100 grms. of soln. between 0° and 100° , where the solid phase is $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, is

MgCl_2	0°	10°	20°	40°	60°	80°	100°
	34.5	34.9	35.3	36.5	37.9	39.8	42.2

The solubility curve covering the range between 50° and 200° is illustrated in Fig. 11. The solubility with ice as the solid phase falls from 11.1 per cent. at -10° to the eutectic B with the solubility 20.6 per cent. at -33.6° ; when the solid phase is a mixture of ice and $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$; the solubility with $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ as the solid phase then rises to 31.6 per cent. at -16.8° , C , where the solid phase is a mixture of $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ and $\alpha\text{-MgCl}_2 \cdot 8\text{H}_2\text{O}$; at -17.4° , H , solubility 32.3 per cent. the solid phases are $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ and $\beta\text{-MgCl}_2 \cdot 8\text{H}_2\text{O}$; at -19.4° , K , solubility 33.3 per cent., the solid phases are $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; at -9.6° , J , solubility 34.9 per cent., the solid phases are $\beta\text{-MgCl}_2 \cdot 8\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; at -3.4° , E , solubility 34.4 per cent., the solid phases are $\alpha\text{-MgCl}_2 \cdot 8\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, and the last-named salt is the solid phase from -3.4° to 116.7° , F , when the solubility is 46.2 per cent., and the solid phases are $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$. At 152.6° , the solubility is 49.1 per cent., and the solid phase is $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$; at 181.5° , G , solubility 55.8 per cent., the solid phases are $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$. At 186° the solubility is 56.1 per cent., and the solid phase is $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$. The maximum in the curve at -16.4° , D , represents the m.p. of $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$. The system at H , J , K , is not stable and represent undercooled soln.

FIG. 11.—Solubility Curves of Magnesium Chloride.

and the solid phase is $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$; at 181.5° , G , solubility 55.8 per cent., the solid phases are $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$. At 186° the solubility is 56.1 per cent., and the solid phase is $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$. The maximum in the curve at -16.4° , D , represents the m.p. of $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$. The system at H , J , K , is not stable and represent undercooled soln.

There are at least six different hydrates of magnesium chloride, indicated in Fig. 11. J. H. van't Hoff and W. Meyerhoffer⁵ found that **dodecahydrated magnesium chloride**, $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$, is formed when a soln. with more than 12 and less than 20 mols of water per mol of MgCl_2 , is cooled to -30° or -35° ; or by adding a piece of solid carbon dioxide to an under-cooled soln. $\text{MgCl}_2 + 12\text{H}_2\text{O}$ at -20° . A. Bogorodsky cooled a soln. of $\text{MgCl}_2 + 10\text{H}_2\text{O}$ at -20° , and added a little of a soln. $\text{MgCl}_2 + 12\text{H}_2\text{O}$ cooled below -20° . This salt melts at -16.7° to a clear liquid. The crystals are lighter than the mother liquid, says A. Bogorodsky, and it is not usual for an increase in volume to be observed in the formation of a hydrate. J. H. van't Hoff and W. Meyerhoffer prepared **octohydrated magnesium chloride**, $\text{MgCl}_2 \cdot 8\text{H}_2\text{O}$, by allowing a sat. soln. of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ to stand in contact with the solid phase between -15° and -20° ; or by cooling a soln. of $\text{MgCl}_2 + 10\text{H}_2\text{O}$ to -20° , and removing the mass from the freezing mixture, the dodecahydrated salt disappears and the octahydrated salt remains as a coarse crystalline powder which when mixed with the original soln., and cooled to -10° or -12° , forms thick crystalline plates, which decompose at -3.4° ; A. Bogorodsky says -9.8° . The

range of its existence extends from -16.7° to -3.4° . **Hexahydrated magnesium chloride**, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, crystallizes from aq. soln. between -3.4° and 116.67° . According to J. C. G. de Marignac, it forms prismatic monoclinic crystals with axial ratios $a:b:c=1.348:1:0.818$, and $\beta=96^{\circ} 39'$. E. Filhol gives the sp. gr. 1.558 at ordinary temp., and for bischofite, C. Ochsénius gives 1.65; at -188° , J. Dewar found a sp. gr. 1.6039, and he computes the mean coeff. of thermal expansion between 17° and -188° to be 0.0001072. J. H. van't Hoff and H. M. Dawson have examined the lowering of the f.p. of this salt in the presence of ammonium and alkali chlorides; with potassium sulphate there is a raising of the f.p. owing to the formation of kieserite; hexahydrated magnesium bromide forms mixed crystals with hexahydrated magnesium chloride. The crystals deliquesce in air, and W. Müller-Erbach found the vap. press. to be from 0.012 to 0.016 of that of pure water. P. Bary states that the crystals are phosphorescent when exposed to Röntgen's or Becquerel's rays. H. Davy noted that when this salt is dehydrated, it loses hydrogen chloride, forming magnesium oxide along with the chloride. According to R. Brandes, the crystals begin to lose hydrogen chloride at 106° , they partially melt at 112° , and completely melt at 119° . C. Przibylla gives 116° — 118° for the m.p. of bischofite. The phenomena attending the dehydration of this salt have been previously discussed. H. Lescœur prepared **tetrahydrated magnesium chloride**, $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$, by passing hydrogen chloride into a soln. of magnesium chloride; P. Sabatier, and W. Müller-Erbach, by exposing the hexahydrated salt to a dry atm.; J. H. van't Hoff and W. Meyerhoffer, by drying the hexahydrated salt at 100° to a constant weight; or by melting the hexahydrated salt at 130° in a current of air; when the composition approximates to $\text{MgCl}_2 + 5\text{H}_2\text{O}$, cooling slowly to 117° ; warming to 150° and pouring off the mother liquid. A. Ditte made **dihydrated magnesium chloride**, $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$, by saturating with hydrogen chloride a water-cooled soln. of magnesium chloride; and by adding anhydrous magnesium chloride to conc. hydrochloric acid without allowing the temp. to rise. J. H. van't Hoff and W. Meyerhoffer made the dihydrated salt by passing dry hydrogen chloride over the tetrahydrated salt at 140° . The crystalline plates are very deliquescent, and, according to W. Müller-Erbach, have 0.0013th of the vap. press. of water. W. Moldenhauer made **monohydrated magnesium chloride**, $\text{MgCl}_2 \cdot \text{H}_2\text{O}$, by passing hydrogen chloride over the hexahydrated-salt for 4–6 hrs. at 135° until there is no further loss in weight; the same result was obtained by 12–14 hrs. heating at 110° .

The **specific gravity** of aq. soln. of magnesium chloride has been determined by D. I. Mendeléeff,⁶ R. Engel, P. Kremers, H. Schiff, A. C. Oudemans, and G. T. Gerlach at 15° , and by O. Pulvermacher, H. T. Barnes and A. P. Scott, at 0° and 20° . According to G. T. Gerlach, at 15° ,

Per cent. MgCl_2 .	1	5	10	15	20	25	30	35
Sp. gr.	1.0084	1.0412	1.0859	1.1311	1.1780	1.2273	1.2794	1.3340

W. Biltz gave 2.325 at $25^{\circ}/4^{\circ}$ for the sp. gr. of fused magnesium chloride, and 2.316 for the unfused porous salt. According to G. J. W. Bremer, an empirical relation between the sp. gr. D and the percentage composition p is $D=1+0.0091729p+0.00005507p^2$; and the sp. gr. D at the temp. θ° , is $D=D_0(1-a\theta-b\theta^2)$, where D represents the sp. gr. at 0° , and a and b constants, the former of which is greater in value and the latter smaller in value the more conc. the soln. The expansion curves of the different soln. intersect at approximately 60° . According to N. A. Tschernay, unit volume of a soln. $\text{MgCl}_2 + 50\text{H}_2\text{O}$ at θ° becomes $v=1+0.0001394\theta+0.000002892\theta^2$, and for $\text{MgCl}_2 + 100\text{H}_2\text{O}$, $v=1+0.0000688\theta+0.0003922\theta^2$. J. Wagner's values for the **viscosities** of $\frac{1}{2}N$ -, $\frac{1}{3}N$ -, $\frac{1}{4}N$ -, and N -soln. of magnesium chloride are respectively 1.026, 1.0445, 1.0940, and 1.2015—water unity. O. Pulvermacher also made some measurements. F. E. Bartell and O. E. Madison studied the **osmosis** of soln. of magnesium chloride through animal membranes; and F. E. Bartell and L. B. Sims, through collodion. F. E. Bartell and D. C. Carpenter also measured the rate of osmosis.

According to J. C. G. de Marignac,⁷ the **specific heat** at 22·52° of a soln. of one mol of magnesium chloride in n mols of water is:

n	15	25	50	100	200H ₂ O
Sp. ht.	0·6824	0·7716	0·8665	0·9235	0·9594
Mol. ht.	249·4	421·0	862	1750	3545

G. Jäger found the **heat conductivities** of 11, 14·5, 22, and 29 per cent. soln. of magnesium chloride are respectively 94·9, 91·7, 89·0, and 85·4 (water=100). According to W. Müller-Erbach, the **vapour pressure** of a sat. soln. of magnesium chloride is about 0·27th that of water. S. Skinner has measured the **boiling points** of aq. and alcoholic soln. of magnesium chloride; and E. M. Baker and V. H. Waite found that U. Dühring's rule applies to the boiling of aq. soln. of magnesium chloride. H. C. Jones and F. H. Getman, and J. H. van't Hoff measured the **freezing points** of the soln.

The refraction and dispersion of soln. of magnesium chloride have been investigated by P. Barbier and L. Roux.⁸ For the difference between the **refractive index** of the soln., μ , and that of water, μ_0 , for soln. with $\frac{1}{2}$ MgCl₂ per v litres, D. Dijken found when $v=1$, $\mu-\mu_0=0\cdot011957$; and when $v=128$, $\mu-\mu_0=0\cdot0001013$. O. Pulvermacher measured the refractive index of soln. of magnesium chloride. The **electrical conductivity** has been measured by S. Arrhenius,⁹ P. Walden, and others. H. C. Jones and co-workers found for the mol. conductivity, μ , and the percentage **degree of ionization**, α , of soln. of magnesium chloride with a mol of the salt in v litres of water:

v	4	8	32	128	512	2048	4096
μ_0	80·2	87·6	99·9	110·3	115·7	120·3	123·5
μ_{65°	280·6	303·8	364·8	401·6	433·1	465·6	—
α_0	64·9	70·9	80·9	89·2	93·7	97·3	100·0
α_{65°	60·3	65·3	78·4	86·3	93·0	100·0	—

The temp. coeff. of the conductivity were also computed by H. C. Jones and A. P. West; and the degree of ionization, by G. Kümmell, and K. Drücker. S. Arrhenius computed the **heat of ionization** in a 0·1 eq. soln. at 35° to be -651 cal. Data for the **transport numbers** of the ions have been measured by W. Hittorf, W. Bein, A. Chassy, and B. D. Steele; and S. von Lasezinsky and S. von Gorsky worked with soln. of magnesium chloride in pyridine. F. E. Bartell and D. C. Carpenter measured the **difference of potential** of water and soln. of magnesium chloride separated by a permeable membrane. S. Meyer gave $-0\cdot420 \times 10^{-6}$ units per grm. or $-0\cdot044 \times 10^{-6}$ units per mol for the **magnetic susceptibility** of anhydrous magnesium chloride, and for the hexahydrated salt, $-0\cdot347 \times 10^{-6}$ units per grm. or $-0\cdot092 \times 10^{-6}$ units per mol.

According to F. Margueritte,¹⁰ gaseous *hydrogen chloride* does not precipitate magnesium chloride from its aq. soln., but R. Engel, and A. Ditte showed that this statement is erroneous; the solubility of magnesium chloride is considerably diminished by hydrogen chloride. Expressing the concentrations in grams per 100 c.c. of soln., R. Engel found at 0°,

Per cent. HCl	0	1·49	3·46	6·20	10·39	5·31	21·42	27·71
Per cent. MgCl ₂	47·42	45·48	42·86	39·30	33·83	28·64	22·03	15·20

and a soln. sat. with hydrogen chloride dissolves 6·5 per cent. of magnesium chloride. The solubility of magnesium chloride in the presence of other salts has been investigated by R. Löwenherz¹¹ and by J. H. van't Hoff and co-workers in connection with their studies on the Stassfurt deposits.

Alcohol of sp. gr. 0·90 and 0·871 dissolves respectively 20 and 50 parts of magnesium chloride per 100 c.c. of solvent. S. E. Simon¹² found that heat is evolved when anhydrous magnesium chloride is allowed to act on dry methyl or ethyl alcohol, and on cooling the soln. with a freezing mixture compounds with alcohol

of crystallization separate in deliquescent crystals—*e.g.* **magnesium chloride hexamethyl-alcoholate**, $\text{MgCl}_2 \cdot 6\text{CH}_3\text{OH}$; and **magnesium chloride hexa-ethyl-alcoholate**, $\text{MgCl}_2 \cdot 6\text{C}_2\text{H}_5\text{OH}$. L. Kahlenberg and F. C. Kraushoff find the very low solubility of magnesium chloride in anhydrous *pyridine* and its greater solubility in pyridine with 3 or 4 per cent. of water resembles that of calcium and strontium chlorides in the same menstruum.

According to W. S. Clark,¹³ magnesium chloride volatilizes when heated in a stream of *ammonia*, leaving a residue of magnesium oxide; the sublimate is **magnesium tetrammino-chloride**, $\text{MgCl}_2 \cdot 4\text{NH}_3$, which on exposure decomposes rapidly with the loss of ammonia, but which can be sublimed in an atm. of ammonia. **Magnesium hexammino-chloride**, $\text{MgCl}_2 \cdot 6\text{NH}_3$, analogous with calcium hexammino-chloride, was made by F. Ephraim; according to C. Matignon, the heat of dissociation into **magnesium diammino-chloride**, $\text{MgCl}_2 \cdot 2\text{NH}_3$, and ammonia at 142° is 13.07 Cals. According to W. Biltz and G. F. Hüttig, the dissociation press. of the hexammines could not be determined because of the formation of mixed crystals or solid soln. of two amines. G. Spacu and R. Ripan obtained a colourless crystalline powder of **magnesium pentammino-aquachloride**, $[\text{Mg}(\text{NH}_3)_5\text{H}_2\text{O}]\text{Cl}_2$, by passing ammonia into an alcoholic soln. of magnesium chloride at ordinary temp. W. Biltz and G. F. Hüttig found that the heat of formation and absolute temp. at which the dissociation press. of magnesium diammino-chloride is 100 mm. are respectively 17.9 Cals. and 495° ; similarly for **magnesium ammino-chloride**, $\text{Mg}(\text{NH}_3)\text{Cl}_2$, 20.8 Cals. and 573° ; G. N. Antonoff made the double compound of magnesium chloride with hydroxylamine, **magnesium hydroxylamine chloride**, $\text{MgCl}_2 \cdot 2\text{NH}_2\text{OH} \cdot 2\text{H}_2\text{O}$. H. Niggemann found that when a mixture of air and ammonia was passed into a soln. of 50 grms. of hexahydrated magnesium chloride in 50 c.c. of water at 90° , a precipitate of magnesium hydroxide appeared in about 15 mins. The soln. still contained 40.5 grms. of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ when sat. with ammonia. A mixture of ammonia and carbon dioxide gave an immediate precipitation of magnesium carbonate. G. Spacu made complex salts of magnesium chloride with pyridine and triethylene diammine.

The ready hydrolysis of magnesium chloride soln., as in the case of soln. of beryllium chloride, has led to the production of a number of basic chlorides or **magnesium oxychlorides**. The arguments for the individuality of these products have been based on chemical analyses and are not therefore satisfactory in the light of our present knowledge.¹⁴ The crystalline precipitate, deposited by ammoniacal soln. of magnesium chloride, after washing with water gave G. E. Davis numbers in agreement with $5\text{MgO} \cdot \text{MgCl}_2 \cdot 13\text{H}_2\text{O}$; G. Krause obtained a product $10\text{MgO} \cdot \text{MgCl}_2 \cdot 18\text{H}_2\text{O}$; and C. Bender, $5\text{MgO} \cdot \text{MgCl}_2 \cdot x\text{H}_2\text{O}$, and $9\text{MgCl}_2 \cdot x\text{H}_2\text{O}$. G. André found that needle-like crystals of a product $\text{MgO} \cdot \text{MgCl}_2 \cdot 16\text{H}_2\text{O}$ separate when a boiling soln. of 400 grms. of hexahydrated magnesium chloride and 20 grms. of magnesium oxide in 500 grms. of water is filtered, and allowed to stand 24 hrs. When the crystals are dried in vacuo, they have the composition $\text{MgO} \cdot \text{MgCl}_2 \cdot \text{H}_2\text{O}$. The crystals are decomposed by water and alcohol. The product $\text{MgO} \cdot \text{MgCl}_2 \cdot \text{H}_2\text{O}$ can be resymbolized $\text{Mg}(\text{OH})_2 \cdot \text{MgCl}_2$, or $\text{Mg}(\text{OH})\text{Cl}$, thus recalling W. Moldenhauer's intermediate product in the action of steam on magnesium chloride between 350° and 500° . The product $\text{MgO} \cdot \text{MgCl}_2$ prepared by calcining to 300° an intimate mixture of eq. proportions of magnesium oxide and ammonium magnesium chloride, can also be symbolized $\text{Cl}-\text{Mg}-\text{O}-\text{Mg}-\text{Cl}$. G. André calculates the heats of formation ($\text{MgO} \cdot \text{MgCl}_2$) to be 7.72 Cals.; ($\text{MgO} \cdot \text{MgCl}_2 + 6\text{H}_2\text{O}_{\text{solid}}$), 1.68 Cals.; ($\text{MgO} \cdot \text{MgCl}_2 + 16\text{H}_2\text{O}$), 1.58 Cals.; and ($\text{MgCl}_2 + \text{Mg}(\text{OH})_2 + 6\text{H}_2\text{O}_{\text{liquid}}$), 13.7 Cals. A mol of the product $\text{MgO} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ dissolves at 9° in dil. hydrochloric acid containing two mols of HCl, with the evolution of 18 Cals.; and under the same conditions, $\text{MgO} \cdot \text{MgCl}_2 \cdot 16\text{H}_2\text{O}$ develops 11 Cals. Since the magnesium oxychlorides are decomposed by washing preparatory to the analysis, and if not washed, they will be contaminated with mother liquid, W. O. Robinson and W. H. Waggaman attempted to determine the composition of the basic chlorides, and the ranges of

conc. of the soln. over which they can exist, by studying the solubility of magnesium hydroxide in solutions of magnesium chloride of different conc. The percentage amounts of magnesium oxide present in soln. of magnesium chloride at 25°, are as follows :

Per cent. MgCl.	• 2.36	6.79	13.14	22.04	28.34	30.04	34.22
MgO.	• 0.00008	0.00048	0.00115	0.00245	0.00230	0.00250	0.0030

The detailed results show that at 25°, up to a conc. of about 10 grms. MgCl₂ per 100 c.c. of soln., the solid is an indefinite solid soln. of magnesium oxide and chloride, and water, and from that conc. up to a sat. soln. of magnesium chloride, the solid phase is a basic magnesium chloride 2MgO.HCl.5H₂O, that is, 3MgO.MgCl₂.11H₂O, or still differently expressed :

The so-called *Sorel's magnesia cement* was described by E. Sorel¹⁵ in 1867, and it is made by mixing calcined magnesia with an aq. soln. of magnesium chloride of sp. gr. 1.16 to 1.26. A mixture of finely powdered, dry, calcined magnesite and dry magnesium chloride—which can be preserved in sealed tin vessels—furnishes the same result when mixed with water. The two substances apparently unite with the development of heat, forming what is presumably a magnesium oxychloride, and A. Krieger, E. Luhmann, and L. Preussner have shown that the resulting cement is a mass of minute interlacing crystals. It is supposed that the magnesium chloride and oxide react in soln., forming a supersat. soln. of oxychloride from which crystals are deposited as in the setting of plaster of Paris. Various formulæ have been assigned to the oxychloride. Taking the mol. ratio MgCl₂:MgO:H₂O, C. Bender gave 1:5:17; G. E. Davis, 1:5:13; and G. Krause 1:10:14 when dried at 110° and 1:10:18 when air-dried. The cement is used for cementing glass and metal, and for making artificial stones, etc.—e.g. the so-called *xyloolith* is a mixture of sawdust, cement, and water. Several methods of preparing the mixture have been patented—e.g. by O. Kraner, F. M. Lyte and J. G. Tatters, etc. F. M. Lyte and J. G. Tatters heated to 300° an intimate mixture of ammonium magnesium chloride, NH₄Cl.MgCl₂, with one-fifth of its weight of magnesium oxide; the residue contained a little less magnesium oxide than corresponded with the formula MgO.MgCl₂. A great many modifications have been patented with calcium or barium compounds as accessory constituents, and with starch, gelatinous silica, etc., admixed with the soln. of magnesium chloride. Prolonged treatment of the cement with boiling water dissolves magnesium chloride leaving behind hard magnesium oxide. M. Y. Seaton and co-workers have discussed the action of free lime on the cement.

In 1789, A. F. de Fourcroy¹⁶ showed that ammonium magnesium chloride could be crystallized from a mixed soln. of the component salts; and K. von Hauer purified the salt by crystallization. The analyses corresponded with the formula for **hexahydrated ammonium magnesium chloride**, NH₄Cl.MgCl₂.6H₂O, or *hexahydrated ammonium trichloro-magnesiate*, NH₄MgCl₃.6H₂O; also called *ammonium carnallite*. C. H. Pfaff obtained crystals of the same salt by evaporating the filtrate from the precipitate obtained by treating a soln. of magnesium chloride with an excess of ammonia; and O. Hautz, by similarly treating the liquid remaining after shaking magnesium oxide with a cold aq. soln. of ammonium chloride. J. C. G. de Marignac found that the double pyramidal rhombic crystals have the axial ratios *a*:*b*:*c*=1.0295:1.07220. Potassium and ammonium carnallites form solid soln. with one another. C. H. D. Bödeker's value for the sp. gr. is 1.456. O. Hautz found the salt loses 10.9 per cent. of water at 100°, and 31.15 per cent. (4H₂O) at 135°. The crystals are deliquescent and melt when heated, losing first water, and then ammonium chloride; finally, magnesium chloride alone remains. The salt is sparingly soluble in water; and the electrical conductivity of aq. soln. has been investigated by H. C. Jones and N. Knight. M. Berthelot and G. André reported a crystalline salt, 2NH₄Cl.5MgCl₂.33H₂O; and G. Linck, 2NH₄Cl.3MgCl₂.20H₂O.

C. Sandonnini¹⁷ found that lithium and magnesium chlorides form solid soln. in all proportions, and that these are stable at low temp. The f.p. curve, Fig. 12, shows a minimum with about 40 molar per cent. MgCl₂, at 570°. O. Menge obtained the results shown in Fig. 13, for the f.p. curve of the binary mixtures indicated. A

mixture of sodium and magnesium chlorides has a eutectic at 430° and 55 per cent. of NaCl, and two breaks, one corresponding with sodium magnesium trichloride, $\text{NaCl} \cdot \text{MgCl}_2$, and the other with a compound of uncertain composition. K. Scholich also obtained the two compounds $\text{NaCl} \cdot \text{MgCl}_2$ and $2\text{NaCl} \cdot \text{MgCl}_2$. There is some doubt about the existence of the hydrated sodium magnesium trichloride, $\text{NaCl} \cdot \text{MgCl}_2 \cdot x\text{H}_2\text{O}$. A. B. Poggiale, and A. de Schulten mention this salt, but C. J. B. Karsten, A. J. Balard, and J. N. von Fuchs were unable to dissolve sodium chloride in a soln. of magnesium chloride; and they found that on cooling a boiling sat. soln. of the two salts, crystals of sodium chloride alone separated out. C. Schröder obtained only mixtures of the component salts by passing hydrogen chloride into soln. of magnesium chloride with sodium or potassium chloride.

Figs. 12 to 16.—Freezing-point Curves of Binary Systems of Magnesium Chloride with Lithium, Sodium, Potassium, Cuprous, and Silver Chlorides.

O. Menge found the f.p. curve of mixtures of magnesium and potassium chlorides has two maxima, Fig. 14, at 485° and 437° corresponding respectively with the m.p. of potassium magnesium trichloride, $\text{KCl} \cdot \text{MgCl}_2$, and potassium magnesium tetrachloride, $2\text{KCl} \cdot \text{MgCl}_2$. The existence of these compounds was confirmed by a microscopic examination of the products. J. Valentin obtained only $\text{MgCl}_2 \cdot \text{KCl}$ on the f.p. curve, and K. Scholich could confirm only the same compound; he studied the ternary system $\text{MgCl}_2 - \text{KCl} - \text{NaCl}$. The solubility of magnesium chloride in soln. of potassium chloride was measured by H. Precht and B. Wittjen, J. H. van't Hoff and W. Meyerhoffer, W. Feit and C. Przibylla, and W. B. Lee and A. C. Egerton. W. B. Lee and A. C. Egerton studied the ternary system $\text{KCl} - \text{MgCl}_2 - \text{H}_2\text{O}$ at 25° . Hexahydrated **potassium magnesium trichloride**, $\text{KCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, or hexahydrated *potassium trichloro-magnesiates*, $\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$, occurs in the Stassfurt and other salt deposits. H. Rose¹⁸ identified the mineral in the Stassfurt deposits with the double salt which J. von Liebig had found to be deposited from the mother liquors of the brines from the Salzhausen during a winter's cold, and which A. Marcet had previously obtained from the mother liquors in the evaporation of sea-water. In order to indicate that the double salt occurs as a mineral species, H. Rose named it **carnallite**, in honour of R. von Carnall. C. F. Rammelsberg thought that the double salt deposited from mixed soln. of the component salts belonged to the hexagonal system, but J. C. G. de Marignac, and A. des Cloizeaux showed that the artificial, and A. des Cloizeaux, F. Hesselberg, and C. Busz that the natural, crystals belong to the rhombic system, and have axial ratios $a : b : c = 0.59304 : 1 : 0.69758$. F. Bischof's value for the sp. gr. of natural carnallite is 1.615; E. Reichardt's, 1.60; and C. Przibylla's, as a mean of eleven determinations at 19.4° (water at 4° unity), with the weighings reduced to those in vacuo, 1.6018. H. H. Kunze studied the sp. gr. and the m.p. of mixtures of carnallite and potassium chloride. J. H. van't Hoff and W. Meyerhoffer found the m.p. in a sealed tube to be 265° . The double refraction is strong and positive; and C. Busz found the indices of refraction in sodium light to be $\alpha = 1.46658$; $\beta = 1.47529$; $\gamma = 1.49371$. According to F. Beijerinck, carnallite is a non-conductor of electricity. F. Rüdorff examined the diffusion of soln. of carnallite; and H. H. Kunze, H. C. Jones and N. Knight their electrical conductivity.

J. von Liebig¹⁹ noticed that the crystals of carnallite deliquesce and then

decompose on exposure to air leaving a residue of potassium chloride, and magnesium chloride in soln.; and A. Marcet, that alcohol extracts magnesium chloride leaving behind potassium chloride. Carnallite is thus partly decomposed in contact with a little water; at 25° about 85 per cent. is decomposed in agreement with the symbols: $\text{KCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O} + 7 \cdot 8\text{H}_2\text{O} = 0 \cdot 84\text{KCl} + (\text{MgCl}_2, 0 \cdot 16\text{KCl}, 13 \cdot 8\text{H}_2\text{O})$, where the bracketed term represents the composition of the soln. At temp. below -21° , carnallite cannot exist in contact with its soln., for it forms potassium chloride and dodecahydrated magnesium chloride; at that temp. there is a reversible reaction $\text{KCl} + \text{MgCl}_2 \cdot 12\text{H}_2\text{O} \rightleftharpoons \text{KCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O} + 6\text{H}_2\text{O}$; the upper temp. limit for carnallite is $167 \cdot 5^{\circ}$. This limiting temp. is reduced to $152 \cdot 5^{\circ}$ if magnesium chloride be present. The solubility curve AB of mixtures of $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ and KCl , is shown diagrammatically in Fig. 17; it extends from the eutectic temp. up to B , -21° , the temp. at which carnallite is formed, when two solubility curves BC and BD appear—the one curve, BC , represents sat. soln. of carnallite in the presence of hydrated magnesium chloride—the particular hydrate depending on the temp.; the other, curve, BD , sat. soln. of carnallite in the presence of potassium chloride. The curve BC ends at C , $152 \cdot 5^{\circ}$, the upper limiting temp. for the existence of carnallite in the presence of magnesium chloride—at this temp., $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$; while the curve BD ends at D , $167 \cdot 5^{\circ}$, where the

FIG. 17.—Diagrammatic Representation of the Region of Existence of Carnallite.

sat. soln. has magnesium chloride and water in the same proportion as carnallite. The curve DC represents sat. soln. of carnallite and potassium chloride with less and less water than is represented by the formula of carnallite. These three curves enclose a region BCD within which carnallite can exist in contact with the soln. indicated. The equilibrium conditions of potassium and magnesium chloride are more precisely indicated by the diagram in connection with the chapter on the Stassfurt deposits (*vide* potassium).

W. Feit and K. Kubierschky,²⁰ and H. Erdmann, crystallized *rubidium carnallite*, or **rubidium magnesium chloride**, $\text{RbCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, from a mixed conc. soln. of the constituent salts, and measured the mutual solubility of rubidium and magnesium chlorides. Unlike carnallite, rubidium carnallite is decomposed neither by cold nor by hot water. H. L. Wells and G. F. Campbell also prepared colourless rectangular plates or flat prisms of *cæsium carnallite*, or **cæsium magnesium chloride**, $\text{CsCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, by crystallization from soln. of its component salts. Double salts of a different composition were not obtained by varying the proportions of the component salts. O. Menge found that magnesium chloride forms a simple eutectiferous series with cuprous or silver chloride, Figs. 15 and 16, and from E. Chauvenet, P. Job, and G. Urbain's examination of the thermal effects attending the admixture of soln., they inferred that the double salts **cupric trimagnesium decachloride**, $2\text{CuCl}_2 \cdot 3\text{MgCl}_2$, and **cupric dimagnesium decachloride**, $3\text{CuCl}_2 \cdot 2\text{MgCl}_2$, exist in soln.

According to O. Menge, mixtures of calcium and magnesium chlorides furnish a simple V-eutectic at 621° and 42·8 per cent. of calcium chloride. Solid soln. appear at the calcium chloride end of the series. C. Sandonnini²¹ observed no solid soln. with mixtures of strontium and magnesium chlorides, but there is a eutectic at 535° , and 50 molar per cent. of strontium chloride. With mixtures of magnesium and barium chlorides, there is a eutectic at 556° and 36 molar per cent. of barium chloride; and with greater proportions of the latter salt, there is an arrest in the cooling curve at 590° , and at the eutectic, 556° ; only the upper arrest occurs with more barium chloride, and when still more is added the upper arrest is lowered

down to that of the eutectic. This phenomenon is taken to indicate the production of a compound of barium and magnesium chlorides which decomposes on fusion.

In 1856, C. F. Rammelsberg found a mineral in the Stassfurt salts whose analysis corresponded with **calcium dimagnesium chloride**, $\text{CaCl}_2 \cdot 2\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$, or $\text{Ca}(\text{MgCl}_3)_2 \cdot 12\text{H}_2\text{O}$, and he named it *tachhydrite*, and afterwards (1860) abbreviated it to tachydrite—from *ταχύς*, rapid; *ὑδωρ*, water—in reference to its great hygroscopicity. The relation of tachydrite to carnallite is evident by doubling the formula of the latter; thus, carnallite, $\text{K}_2(\text{MgCl}_3)_2 \cdot 12\text{H}_2\text{O}$; tachydrite, $\text{Ca}(\text{MgCl}_3)_2 \cdot 12\text{H}_2\text{O}$, where the two univalent atoms of potassium replace the bivalent atom of calcium. A. de Schulten made artificial crystals of this salt by concentrating a mixed aq. soln. of 200 grms. of anhydrous calcium chloride and 150 grms. of hexahydrated magnesium chloride on a water-bath until the liquid crystallized on cooling. A. des Cloizeaux showed that the crystals are rhombohedral (hexagonal); and, according to P. Groth, they have the axial ratio $a:c=1:1.900$. F. Bischof's value for the sp. gr. is 1.671; E. Erdmann's, 1.867; and J. H. van't Hoff's value is 1.6655, the mean of 1.6634 and 1.6683. R. Görgéy, and H. E. Boeke give the hardness 1 to 2—that of gypsum. A. des Cloizeaux says the double refraction is negative, and the mean refractive index, according to R. Görgéy, is 1.52. The salt is soluble in water—100 parts of water at 18.75° dissolve 160.3 parts of the salt. J. H. van't Hoff found the mol. ht. of soln. to be 23.55 Cals., and in the formation of a gram of tachydrite 33.82 Cals. are absorbed. F. Bischof found the temp. rises from 18.75° to 26.5° when 20 parts of tachydrite are dissolved in 80 of water.

The conditions of equilibrium have been largely determined by J. H. van't Hoff and his co-workers.²² Below 22° a soln. of tachydrite decomposes into its component salts, so A. de Schulten's soln. furnishes tachydrite, provided the temp. is over 22° . At this temp. there is the balanced reaction: $\text{CaCl}_2 \cdot 6\text{H}_2\text{O} + 2(\text{MgCl}_2 \cdot 6\text{H}_2\text{O}) = \text{CaCl}_2 \cdot 2\text{MgCl}_2 \cdot 12\text{H}_2\text{O} + 6\text{H}_2\text{O}$. The temp. of formation is raised 0.017° per atm. increase of press.

At temp. exceeding 168° tachydrite partially melts and decomposes. The conditions of equilibrium are represented graphically by J. H. van't Hoff's diagram, Fig. 18. The curve CA is the sat. curve of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; C is at 16.7° ; A , the formation temp. of tachydrite, is at 21.95° . The curve AN is the sat. curve of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ and tachydrite; the curve ends at N , the transformation

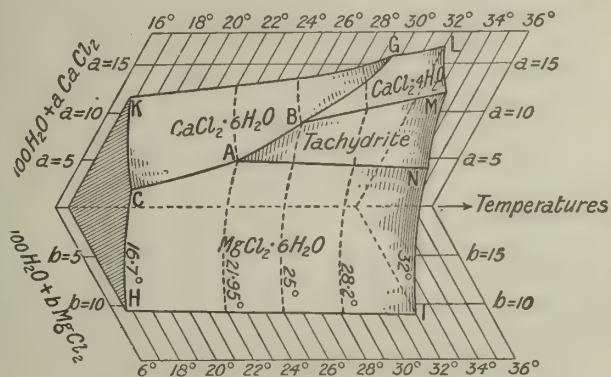

FIG. 18.—Equilibrium Curves for the System $\text{CaCl}_2\text{—MgCl}_2\text{—H}_2\text{O}$, after J. H. van't Hoff.

temp. of $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$. The curve AB likewise represents the sat. curve of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ and tachydrite; and BM , of $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$ and tachydrite; B , 25° is the transformation temp. of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ into $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$. The curve BG is the sat. curve of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$; the curve HI is the sat. curve of magnesium chloride alone— $H=16.7^\circ$, $I=32^\circ$; the curve KG and GL represents the sat. curve of calcium chloride alone and at G , 29.44° , $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ passes into $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$. The region $MBAN$ is sat. with tachydrite; $LGBM$, with $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$; $HCANI$, with $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; and $KCABG$, with $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$. Lines represent soln. sat. by the salts indicated by the adjoining regions; and points represent soln. sat. by the salts of the adjacent regions. The

temp., $116-67^{\circ}$, of the transformation of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ into $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ is not much affected by the presence of tachydrate, but the temp. of the transformation of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ into $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$ is lowered by the presence of tachydrate from 29.2° to 25° . The ternary system $\text{MgCl}_2\text{—CaCl}_2\text{—H}_2\text{O}$ at 25° was studied by W. B. Lee and A. C. Egerton. J. Valentin obtained **potassium barium tetrachloride**, $2\text{KCl} \cdot \text{BaCl}_2$, on the f.p. curve; and studied the ternary system $\text{BaCl}_2\text{—KCl—MgCl}_2$.

§ 9. Magnesium Bromide

Magnesium bromide occurs in soln. in sea-water and brine springs. It has been reported in the Stassfurt salts, and A. J. Balard¹ extracted magnesium bromide from sea-water in 1826, and from kelp salts. The waters of the Dead Sea are particularly rich in magnesium bromide.

Bromine water slowly attacks magnesium with the evolution of hydrogen, but, according to J. A. Wanklyn and E. T. Chapman, dry liquid bromine had no perceptible action on magnesium after a year's contact. Magnesium burns in bromine vapour forming magnesium bromide, but, says R. Bunsen, the combustion is not so vigorous as in chlorine. O. Lerch conducted bromine vapour over magnesium at a red heat, when the mass became incandescent; and if any metal remained unattacked it floated as small spheres on the surface of the specifically heavier bromide. H. Gautier and G. Charpy also made magnesium bromide by direct combination of the elements. C. Löwig, and G. S. Sérullas say that a part of the magnesium bromide is carried forward by the stream of bromine vapour mixed with carbon monoxide. C. F. Rammelsberg neutralized hydrobromic acid with magnesium oxide; F. Klein neutralized the acid liquid obtained from bromine water and phosphorus by *magnesia alba*; and O. Lerch treated magnesium and water with liquid bromine. The evaporation of the resulting soln. furnishes crystals of hexahydrated magnesium bromide, $\text{MgBr}_2 \cdot 6\text{H}_2\text{O}$. If the aq. soln. of magnesium bromide be mixed with ammonium bromide, and then evaporated to dryness, the resulting ammonium magnesium bromide gives anhydrous magnesium bromide when heated until the ammonium bromide is all expelled; otherwise, some hydrogen bromide escapes during the dehydration. O. Lerch also heated a mixture of the crystalline salt with ammonium bromide so as to prevent hydrolytic dissociation.

Anhydrous magnesium bromide, said G. S. Sérullas,² is a white crystalline non-volatile substance whose crystals, according to O. Lerch, resemble those of magnesium chloride. G. F. Hüttig gave 3.722 at $25^\circ/4^\circ$ for the **specific gravity** of anhydrous magnesium bromide, and W. Biltz, the mol. vol. as 49.48 ; and for the sp. gr., 3.72 at $25^\circ/4^\circ$. The **melting point**, according to T. Carnelley, is 695° . W. Hampe found the molten mass to be a good conductor of electricity. M. Berthelot's value for the **heat of formation** is (Mg, Br_2) 140 Cals. nearly; and N. N. Beketoff's,

121.7 Cals. ; J. Thomsen's value for $(\text{Mg}, \text{Br}_2, \text{aq.})$ is 160.5 Cals. ; and N. N. Beke-
toff's value for $(\text{MgBr}_2, \text{aq.})$ 43.3 Cals.

According to O. Lerch, magnesium bromide is not decomposed when heated to its m.p. provided air be excluded, but if oxygen be present, bromine is evolved and magnesium oxide is formed. When the solid or a conc. soln. is treated with conc. sulphuric acid, bromine is evolved, and, added C. Löwig, if a dil. soln. be distilled with sulphuric acid, hydrobromic acid is formed. O. Lerch said that anhydrous magnesium bromide deliquesces in air more rapidly than magnesium bromide, and that it dissolves in water with a hissing noise.

The **solubility** determinations of magnesium bromide have been made by B. N. Menshutkin,³ A. Etard, F. Mylius and R. Funk, and I. Panfiloff. A. Etard's results are considered to be too high, and where his data cross with those of F. Mylius and R. Funk, there is a difference of 7 to 8 per cent. The data of the latter agree with those of B. N. Menshutkin, whose results, expressed in grams of MgBr_2 per 100 grms. of soln., are as follows :

	-10°	0°	20°	40°	60°	80°	100°	120°	140°	160°
MgBr_2 . . .	47.2	47.9	49.1	50.4	51.8	53.2	54.6	56.0	58.0	62.0

The solid phase over this range of temperature is **hexahydrated magnesium bromide**, $\text{MgBr}_2 \cdot 6\text{H}_2\text{O}$, so that at ordinary temp. this salt crystallizes from aq. soln. The solubility of this salt is thus greater than that of the corresponding hexahydrated chloride. The equilibrium diagram has not yet been worked out. I. Panfiloff believes that at -12° there is a transition temp. below which decahydrated magnesium bromide, $\text{MgBr}_2 \cdot 10\text{H}_2\text{O}$, is formed ; and he obtained crystals in thin plates by cooling 45–47.8 per cent. soln. of MgBr_2 to -18° , and drying them below 0° by press. between filter-paper. The crystals of the decahydrated salt melt between 11.5° and 12.5° with partial decomposition : $\text{MgBr}_2 \cdot 10\text{H}_2\text{O} \rightleftharpoons \text{MgBr}_2 \cdot 6\text{H}_2\text{O} + 4\text{H}_2\text{O}$.

Hexahydrated magnesium bromide forms transparent prisms and needles which, according to J. H. van't Hoff and H. M. Dawson, and H. E. Boeke, are isomorphous with those of the corresponding chloride ; the two salts form mixed crystals with one another. I. Panfiloff gives the **melting point** of hexahydrated magnesium bromide as 152° ; B. N. Menshutkin, 164° ; and F. Mylius and R. Funk, 165° . P. Bary found the salt to be fluorescent when exposed to Röntgen's or Becquerel's rays. H. Lesceur thought that his measurements of the vap. press. of the hexahydrate at different temp. corresponded with the formation of monohydrated *magnesium bromide*, $\text{MgBr}_2 \cdot \text{H}_2\text{O}$, but no other evidence is yet forthcoming of the existence of this salt. According to A. J. Balard, the crystals of hexahydrated magnesium bromide deliquesce in air, and when heated decompose into hydrogen bromide and magnesium oxide. J. L. Kreider showed, however, that approximately two of the six mols of the water may be removed from the hexahydrate between 70° and 160° , without any appreciable loss of hydrogen bromide ; any further loss of water, when the salt is heated in air, is attended by a loss of hydrogen bromide—an atm. of hydrogen bromide inhibits the loss of hydrogen bromide by the salt. J. L. Kreider accordingly argued that in the molecule of hexahydrated magnesium bromide two of the six mols of water are differently placed from the other four ; and he suggests the graphic formula :

There is yet no evidence of the formation of a tetrahydrated salt.

According to F. Mylius and R. Funk,⁴ a soln. sat. at 18° contains 103.4 grms. of MgBr_2 per 100 grms. of water—i.e. 50.8 per cent. of MgBr_2 , or $\text{MgBr}_2 + 9.9\text{H}_2\text{O}$ —and the **specific gravity** is 1.655 (18°). For the sp. gr. of aq. soln. of magnesium bromide at 19.5° , G. T. Gerlach calculated from P. Kremers' data :

Per cent. MgBr_2 . . .	5	10	15	20	30	40	50
Sp. gr.	1.043	1.087	1.137	1.191	1.310	1.451	1.625

D. I. Mendeléeff also made observations on this subject. K. Jauch found the sp. ht. of soln. containing m eq. of magnesium bromide per litre, at 18° , to be

m	0.5	1.0	2.0	3.0	4.0
Sp. ht.	0.9441	0.8941	0.8068	0.7333	0.6688

H. C. Jones and F. H. Getman have investigated the **lowering of the freezing points** of soln.; while H. C. Jones and H. P. Basset have investigated the formation of hydrates in soln. from the lowering of the f.p., and the **electrical conductivities**. P. Walden measured the **equivalent conductivities** of aq. soln. H. C. Jones and co-workers found the mol conductivity, μ , and the percentage **degree of ionization**, α , of a soln. containing a mol of the salt in v litres, to be

v	2	8	32	128	512	2048
μ_{0°	76.34	93.73	104.56	113.52	118.93	127.28
μ_{65°	—	324.4	367.7	412.8	445.5	471.3
α_{0°	59.3	71.6	79.9	86.8	90.9	97.3
α_{65°	—	68.8	78.0	87.6	94.5	100.0

They also measured the temp. coeff. of the conductivities. S. Meyer gave -0.449×10^{-6} units per grm. or -0.083 unit per mol for the **magnetic susceptibility** of anhydrous magnesium bromide.

Magnesium bromide is hydrolyzed by water in a manner analogous to magnesium chloride, and similar remarks apply to the formation of basic salts, or **magnesium oxybromides**. E. Tassilly,⁵ boiled a soln. of 145 grms. of $\text{MgBr}_2 \cdot 6\text{H}_2\text{O}$ in 300 c.c. of water, and added 5 grms. of magnesium oxide, prepared at a low temp., in small quantities at a time. The mixture was finally heated to about 150° , and filtered hot. In a few days, the soln., protected from the air, deposited needle-like crystals of $3\text{MgO} \cdot \text{MgBr}_2 \cdot 12\text{H}_2\text{O}$, which when heated to 120° in a stream of air, freed from carbon dioxide, gave crystals of $3\text{MgO} \cdot \text{MgBr}_2 \cdot 6\text{H}_2\text{O}$. This oxybromide is decomposed by water and alcohol.

W. Biltz and G. F. Hüttig,⁶ and G. Spacu and R. Ripan prepared **magnesium hexamminobromide**, $\text{Mg}(\text{NH}_3)_6\text{Br}_2$; and they found the heat of formation and the temp. at which the dissociation press. is 100 mm. to be respectively 20.1 Cals., and 559° for **magnesium diamminobromide**, $\text{Mg}(\text{NH}_3)_2\text{Br}_2$, and 21.7 Cals., and 606° for **magnesium amminobromide**, $\text{Mg}(\text{NH}_3)\text{Br}_2$. A. de Schulten prepared rhombic prisms of **ammonium magnesium bromide**, $\text{NH}_4\text{Br} \cdot \text{MgBr}_2 \cdot 6\text{H}_2\text{O}$, or hexahydrated **ammonium tribromomagnesiates**, $\text{NH}_4\text{MgBr}_3 \cdot 6\text{H}_2\text{O}$, or **ammonium bromocarnallite** isomorphous with the corresponding potassium salt, $\text{KBr} \cdot \text{MgBr}_2 \cdot 6\text{H}_2\text{O}$, by evaporating an aq. soln. of 30 grms. of ammonium bromide, and 250 grms. of hexahydrated magnesium bromide over sulphuric acid. The rhombic (pseudo-tetragonal) crystals have the axial ratio $a:b=1:1.0255$, and sp. gr. 1.989. The same crystals were made by O. Lerch. G. Kellner studied the binary systems of magnesium bromide with lithium, sodium, and potassium bromides. The products are isomorphous with the corresponding chlorides. No case of dimorphism was observed. The results are summarized in Figs. 19 to 21. Lithium bromide forms solid soln. of limited conc. Sodium and magnesium bromides form a simple eutectiferous series with the eutectic at 431° . Potassium and magnesium bromides form double salts—potassium magnesium tetrabromide, $2\text{KBr} \cdot \text{MgBr}_2$, and potassium magnesium tribromide, $\text{KBr} \cdot \text{MgBr}_2$, which decompose respectively at 348° and 391° , and there is a eutectic between them at 334° . Solid soln. are not formed. A. de Schulten made crystals of **hexahydrated potassium magnesium tribromide**, or **potassium tribromo-magnesiates**, $\text{KMgBr}_3 \cdot 6\text{H}_2\text{O}$, by a method similar to that employed for the ammonium salt. W. Feit first made the same salt by mixing a soln. of 12 grms. of magnesium bromide, sat. at ordinary temp. with a boiling sat. soln. of one grm. of potassium bromide. On cooling, crystals of the last-named salt separated out, but which on standing were transformed into the salt in question. On account of the analogy between this salt and carnallite, it has been called *bromocarnallite*. According to A. de Schulten, it forms transparent prisms belonging to the rhombic (pseudo-tetragonal)

system with axial ratio $a:b=1:1.0255$; the sp. gr. is 2.134 (15°). The crystals of $2\text{KBr}\cdot\text{MgBr}_2\cdot 6\text{H}_2\text{O}$, reported by C. Löwig, could not be made by A. de Schulten, O. Lerch, or W. Feit; they are thought to be a mixture of $\text{KBr}\cdot\text{MgBr}_2\cdot 6\text{H}_2\text{O}$ with some potassium bromide. H. E. Boeke has constructed the equilibrium diagram of potassium and magnesium chlorides and bromides in water at 25° . The mixed crystals of carnallite and bromocarnallite appear in three different modifications: (i) those with from 0 to 12.2 mol per cent. are rhombic pseudo-hexagonal, resembling carnallite; (ii) those with from 12.2 to 85 mols per cent. have the tetragonal form; and (iii) those with 85 to 100 mols per cent. are rhombic pseudo-tetragonal. H. L. Wells and G. F. Campbell made crystals of **cæsium magnesium**

FIGS. 19 to 21.—Freezing-point Curves of Binary Mixtures of Magnesium Bromide with Lithium, Sodium, and Potassium Bromides.

bromide, $\text{CsBr}\cdot\text{MgBr}_2\cdot 6\text{H}_2\text{O}$, by a process similar to that used for the corresponding chloride; the general properties of the two salts were similar.

According to B. N. Menshutkin,⁷ magnesium bromide forms compounds $\text{MgBr}_2\cdot 6\text{CH}_3\text{OH}$ with methyl alcohol; $\text{MgBr}_2\cdot 6\text{C}_2\text{H}_5\text{OH}$ with ethyl alcohol; $\text{MgBr}_2\cdot 6\text{C}_3\text{H}_7\text{OH}$ with propyl alcohol; $\text{MgBr}_2\cdot 6(\text{CH}_3)_2\text{CH}\cdot\text{CH}_2\text{OH}$ with isobutyl alcohol; and $\text{MgBr}_2\cdot 4(\text{CH}_3)_2\text{CHOH}$ in isopropyl alcohol. Similarly, with ether it forms $\text{MgBr}_2\cdot (\text{C}_2\text{H}_5)_2\text{O}$. He also made hexa-compounds with formic and acetic acids; and obtained compounds of magnesium bromide with aniline— $\text{MgBr}_2\cdot 6\text{C}_6\text{H}_5\text{NH}_2$; $\text{MgBr}_2\cdot 4\text{C}_6\text{H}_5\text{NH}_2$; and $\text{MgBr}_2\cdot 2\text{C}_6\text{H}_5\text{NH}_2$ or $\text{MgBr}_2\cdot \text{C}_6\text{H}_5\text{NH}_2$. Magnesium bromide also forms compounds with phenyl hydrazine, etc. The solubility of these salts in the corresponding solvent was also investigated, and in general, the higher the alcohol in the series the smaller the solubility of the corresponding alcoholate.

§ 10. Magnesium Iodide

Small traces of magnesium iodide have been reported in sea-water and in certain saline waters. For example, some mineral springs in Java contain magnesium iodide eq. to 0.012 gm. per litre, and iodine can be obtained from the water by the copper sulphate process. According to R. Bunsen,¹ magnesium burns vigorously in iodine vapour, forming anhydrous magnesium iodide, MgI_2 , but, according to T. L. Phipson, iodine may be distilled from magnesium without appreciable action; O. Lerch also found that magnesium does not react with iodine unless the metal is melted, and he recommends melting the metal in a vertical tube of hard glass, sealed at one end; when solid iodine is dropped on the molten metal, a vigorous reaction occurs with incandescence. Air should be excluded as much as possible or some magnesium oxide will be formed—globules of the unchanged magnesium float on the surface of the heavier iodide. F. Bodroux noted the action of iodine on magnesium in the presence of water; when water is dropped on a mixture of magnesium filings and iodine, the reaction is quite brilliant, and suited for a lecture experiment. O. Lerch made magnesium iodide by heating anhydrous magnesium chloride with ammonium iodide, when ammonium chloride volatilizes, and molten magnesium iodide remains; he obtained a similar result by heating ammonium magnesium iodide with an excess of ammonium iodide, first driving off the water at a relatively low temp. and afterwards subliming the ammonium iodide at a higher temp.

G. F. Hüttig gave 4.244 at 25°/4° for the **specific gravity** of anhydrous magnesium iodide, and W. Biltz gave 65.36 for the mol. vol. and 4.244 to 4.268 for the sp. gr. at 25°/4°. According to O. Lerch, the **melting point** of anhydrous magnesium iodide lies above that of the corresponding bromide, as does magnesium bromide above the corresponding chloride. The crystals are snow white, but they are usually coloured by iodine, because, says O. Lerch, the anhydrous iodide is decomposed at ordinary temp. by atm. oxygen; and M. Berthelot converted the iodide completely into oxide by heating it in oxygen. The anhydrous iodide dissolves in water with a hissing noise, and O. Lerch found the salt is also soluble in alcohol, ether, and methyl iodide; and W. Eidmann says the hydrated salt is soluble in acetone. B. N. Menshutkin obtained a series of compounds of magnesium iodide with methyl and ethyl alcohols, ether, the alkyl esters, and acetic acid— $MgI_2 \cdot 6CH_3OH$; $MgI_2 \cdot 6C_2H_5OH$; $MgI_2 \cdot 2(C_2H_5)_2O$; etc.—analogous to those obtained with magnesium bromide. He also measured the solubilities of these compounds in the corresponding menstrua.

F. Faktor, and J. A. Wanklyn and E. T. Chapman noted that aq., alcoholic, and ethereal soln. of iodine act slowly on magnesium. According to I. Panfiloff,

if hydriodic acid be sat. with freshly precipitated magnesium hydroxide, at ordinary temp., crystals of the octohydrate are formed. O. Lerch found that if the soln. obtained by the joint action of iodine, water, and magnesium be decanted from the basic iodide, and slowly evaporated over sulphuric acid, the liquid becomes brown and furnishes crystals of octohydrated magnesium iodide, $\text{MgI}_2 \cdot 8\text{H}_2\text{O}$. This salt melts at 41° , according to I. Panfiloff; 45° , F. Mylius and R. Funk; $43\cdot5^\circ$, B. N. Menshutkin. It effloresces over sulphuric acid, and deliquesces in air. B. N. Menshutkin showed that hexahydrated magnesium iodide, $\text{MgI}_2 \cdot 6\text{H}_2\text{O}$, is the stable form between 44° and upwards of 200° , and his data for the solubility of magnesium iodide in grms. of MgI_2 per 100 grms. of soln. are:

	0°	20°	40°	43°	50°	90°	140°	160°	200°
MgI_2 . . .	50·0	53·4	57·8	59·4	61·6	62·1	62·5	63·0	64·1
Solid phase . . .	$\text{MgI}_2 \cdot 8\text{H}_2\text{O}$			\rightleftharpoons	$\text{MgI}_2 \cdot 6\text{H}_2\text{O}$				

The m.p. of the octohydrated salt is between 43° and $43\cdot5^\circ$; the hexahydrated salt does not melt in a sealed tube at 180° – 190° , but the walls of the tube begin to get a brown film; and above 200° – 210° , the salt decomposes. Consequently, the anhydrous iodide is not made by the dehydration of the hydrated salt. A comparison of the solubility curves of the three hexahydrated salts— $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; $\text{MgBr}_2 \cdot 6\text{H}_2\text{O}$; and $\text{MgI}_2 \cdot 6\text{H}_2\text{O}$ —shows that in passing from the chloride to the iodide, as is frequently the case with the metal halides, the solubility increases. If an aq. soln. of a mol of MgI_2 in 10 mols of water be cooled to 8° , colourless six-sided crystalline plates of decahydrated magnesium iodide, $\text{MgI}_2 \cdot 10\text{H}_2\text{O}$, are formed which, after drying between filter paper at -4° to -5° , melt at 23° .

According to F. Mylius and R. Funk, a soln. sat. at 18° has a sp. gr. 1·909, and contains 59·7 per cent. of MgI_2 or 148 grms. of MgI_2 per 100 grms. of water. According to G. T. Gerlach, P. Kremers' data give for the sp. gr. of soln. at $19\cdot5^\circ$:

Per cent. MgI_2 . .	5	10	20	30	40	50	60
Sp. gr.	1·043	1·088	1·194	1·32	1·474	1·668	1·915

According to A. Heydweiller, the eq. electrical conductivity with 4, 0·5, and 0·05 gram-eq. per litre at 18° rises from 41·0 to 75·7, and to 94·6 respectively. Data for the **transport numbers** of the ions of magnesium iodide were obtained by W. Hittorf.

F. Ephraim,² and W. Biltz and G. F. Hüttig prepared **magnesium hexammino-iodide**, $\text{Mg}(\text{NH}_3)_6\text{I}_2$; and W. Biltz and G. F. Hüttig found that with **magnesium diammino-iodide**, $\text{Mg}(\text{NH}_3)_2\text{I}_2$, the heat of formation is 22·7 Cals.; and at 636° , the dissociation press. is 100 mm. O. Lerch, and A. de Schulten evaporated a soln. of 15 grms. of ammonium iodide and 125 grms. of hexahydrated magnesium iodide in vacuo over sulphuric acid, and obtained hygroscopic prismatic crystals of **ammonium magnesium iodide**, $\text{NH}_4\text{I} \cdot \text{MgI}_2 \cdot 6\text{H}_2\text{O}$. G. Spacu made complex salts of magnesium iodide with triethylenediammine and diethylenediammine. The corresponding **potassium magnesium iodide**, $\text{KI} \cdot \text{MgI}_2 \cdot 6\text{H}_2\text{O}$, was similar, and was prepared in a similar manner. The sp. gr. of the former was 2·346 (15°) and of the latter 2·547 (15°). The potassium salt has been called *iodocarnallite*, and the ammonium salt *iodo-ammonium carnallite*. H. E. Boeke found that carnallite does not form mixed crystals with iodocarnallite. **Magnesium iodo-chloride**, $\text{MgCl}_2 \cdot 2\text{ICl}_3 \cdot 8\text{H}_2\text{O}$, was made by E. Filhol by triturating conc. hydrochloric acid with magnesium iodate, and by saturating an aq. soln. of magnesium iodide with chlorine, or mixing iodine trichloride with magnesium chloride; and R. F. Weinland and F. Schlegelmilch, by the action of chlorine on a mixture of iodine and magnesium chloride in water. It forms yellow deliquescent needle-like crystals which resemble the potassium analogue: KICl_4 or $\text{KCl} \cdot \text{ICl}_3$. C. K. Tinkler obtained some evidence of the existence of *magnesium polyiodide* from the identity of the absorption spectra of soln. of magnesium iodide and iodine with the spectra of analogous soln. of cadmium, sodium, potassium, barium, zinc, and aluminium.

§ 11. Magnesium Sulphides

L. Kessler ¹ made **magnesium sulphide**, MgS , by the action of hydrogen sulphide on red-hot magnesia, by heating a mixture of magnesium and sulphur, and by plunging burning magnesium in a jar of dry hydrogen sulphide; but F. G. Reichel found that magnesium does not readily combine with molten sulphur, although a little is formed if the sulphur be heated with carbon, or if the two elements be heated in a stream of hydrogen or hydrogen sulphide, and A. Mourlot also obtained the sulphide by heating a mixture of sulphur and magnesium filings in hydrogen; F. G. Reichel, and J. Parkinson, by passing the vapour of sulphur mixed with hydrogen over the red-hot metal. E. Tiede could not get magnesium sulphide prepared by this process free from magnesium by the sublimation of the metal in vacuo; but a highly purified product was obtained by boiling for 3 hrs. in a reflux condenser 10 grms. of the crude sulphide with 100 c.c. of ether freshly distilled from sodium, 10 grms. of ethyl iodide, and a fragment of iodine. Moisture must be excluded. The residue was washed with ether, and dried in a vacuum desiccator on a water-bath. E. Tiede and F. Richter made the anhydrous sulphide by heating the oxide in a current of nitrogen laden with the vapour of carbon disulphide. O. Schumann found very little magnesium sulphide is produced by passing hydrogen sulphide over red-hot magnesium oxide, but A. Mourlot observed a slow transformation by heating the oxide or sulphate at about 1200° in a stream of hydrogen sulphide. E. Tiede had no success by heating anhydrous magnesium sulphate for an hour at 1200° in a stream of hydrogen sulphide, although at 450° water and sulphur were formed. F. Briegleb and A. Geuther obtained the sulphide by the action of the same gas on magnesium nitride. E. Frémy prepared the sulphide mixed with a little polysulphide by passing the vapour of carbon disulphide over red-hot magnesium oxide, and F. G. Reichel found that some carbonyl sulphide is formed at the same time: $\text{MgO} + \text{CS}_2 = \text{MgS} + \text{COS}$, and if the vapour of carbon disulphide is mixed with carbon dioxide, some **magnesium oxysulphide**, MgO.MgS , is formed. According to A. Mourlot, the amorphous sulphide obtained by these methods is converted into the crystalline state by heating it for a few minutes in an electric arc-furnace; and he also obtained crystalline magnesium sulphide by heating a mixture of magnesium chloride and stannous sulphide in the electric arc-furnace. Magnesium sulphide is not obtained by heating the sulphate with carbon, hydrogen, hydrogen sulphide, ammonium sulphide or carbon monoxide. P. Berthier obtained but a small conversion of magnesium sulphate to sulphide by heating the sulphate with carbon, and A. Mourlot said that the conversion is incomplete in the electric arc-furnace.

The colour of the amorphous magnesium sulphide so far prepared varies from pale red to reddish-brown. E. Tiede's sample was reddish-white and amorphous. A. Mourlot stated that the crystals belonged to the cubic system. According to W. L. Bragg, the **X-radiogram** corresponds with a simple cubic lattice with the neighbouring atoms 2.54 Å. apart. S. Holgersson gave 5.078 ± 0.012 Å. The crystalline sulphide has a **specific gravity** 2.79–2.85 at 15°, while the amorphous sulphide has a sp. gr. 2.2 at 15°. P. Sabatier's value for the **heat of formation** ($\text{Mg}, \text{S}_{\text{solid}}$) = 79.6 Cals., and the heat of the reaction : ($\text{MgS}, \text{HCl}_{\text{dil. aq.}}$) = 21.80 Cals. at 13°. E. Tiede prepared a sample free from spectroscopic traces of alkaline earths, and from organic solvents, and when exposed for a few seconds to daylight or arc-light, it became faintly luminous. Less purified samples were more **phosphorescent**. Pure magnesium sulphide, say E. Tiede and F. Richter, is not phosphorescent, but it becomes so by suitable additions of manganese, bismuth, or antimony; the optimum amounts per gram of sulphide are 0.001–0.002 gm. of manganese chloride or sulphate; 0.0024 gm. of basic bismuth nitrate; or 0.0013 gm. of potassium antimonyl tartrate. E. Tiede and A. Schleede discussed the preparation and properties of phosphorescent magnesium sulphide. Magnesium sulphide is more sensitive to the rays of long wave-length. No excitation was observed with **X-rays, radium rays, or ultra-violet light**; but in the **cathode rays**, it gives a lively blue and red fluorescence, with a feeble after-glow.

The amorphous sulphide prepared by F. G. Reichel, and J. Parkinson developed hydrogen sulphide when exposed to moist **air**, and in contact with cold **water**, magnesium hydrosulphide, $\text{Mg}(\text{SH})_2$, is formed. According to E. Frémy, water dissolves magnesium sulphide very sparingly, and on standing hydrogen sulphide is evolved and magnesium hydroxide is precipitated; the action is rapid with warm water. According to A. Mourlot, water does not attack the crystalline sulphide in the cold, but when heated, magnesium oxide and hydrogen sulphide are formed. O. Schumann found that in superheated steam, magnesium sulphide is decomposed, furnishing hydrogen sulphide, sulphur, sulphur dioxide, and magnesium oxide. Magnesium sulphide is not changed by heating it in **hydrogen, coal gas, or carbon monoxide**, but if any polysulphide is present, the excess of sulphur was found by F. G. Reichel to be withdrawn.

According to A. Mourlot, **chlorine** reacts with crystalline magnesium sulphide at 300°, and the mass becomes incandescent with the formation of sulphur chloride and magnesium chloride; **bromine** and **iodine** act at dull redness in a similar way without incandescence. The crystalline sulphide is decomposed in the cold by **hydrogen fluoride** and **hydrogen chloride**; if warm, the mass becomes red hot. The **metalloid chlorides** react with the suitably heated crystalline sulphide, forming the corresponding oxide—the reaction is quite vigorous with **phosphorus trichloride** or with **arsenic trichloride**—**chromyl chloride** behaves similarly. The action of **oxygen** on the warm crystalline sulphide is quite vigorous and sulphur dioxide is formed; **oxidizing agents** also react vigorously with crystalline magnesium sulphide—even **phosphorus pentoxide** is reduced to phosphorus sulphide. F. G. Reichel found that when the vapour of **sulphur** mixed with hydrogen or hydrogen sulphide is passed over amorphous magnesium sulphide, no polysulphide is formed, nor does **carbon disulphide** unite with the sulphide. A. Mourlot found dil. or conc. **sulphuric acid** reacts with crystalline magnesium sulphide with the evolution of hydrogen sulphide; and with cold conc. **nitric acid**, sulphur is separated. The crystalline sulphide is not reduced by **phosphorus** at 1000°, and at a red heat, **boron** and **silicon** have no action. The crystalline sulphide is not reduced by **carbon** when heated for 15 mins. in the electric-arc furnace, no carbide is formed, and no volatilization is perceptible. H. C. Geelmuyden found that **calcium carbide** reduces magnesium sulphide in the electric-arc furnace, and the metal is volatilized. Crystalline magnesium sulphide is reduced by **sodium** without incandescence; but **iron** does not reduce it at a dull red heat. F. G. Reichel also found that if the amorphous sulphide is heated with iron or with **copper**, the

corresponding sulphide is formed, but he did not succeed in isolating magnesium. T. Petitjean has also studied these reactions.

V. Calcegni found 100 c.c. of a cold sat. soln. of magnesium hydroxide dissolved 0.014 grms of sulphur so that the relation is $\text{Mg} : \text{S} = 1 : 2$. The soln. responds to the reactions for sulphides, polysulphides, thiosulphates, and sulphites. According to F. G. Reichel, if magnesium sulphide be warmed with water and sulphur, not to the b.p., a dark yellow liquid is produced which presumably contains magnesium polysulphide. This liquid decomposes when exposed to the air, and gives off hydrogen sulphide, forming sulphur, magnesium hydroxide, and a trace of magnesium thiosulphate. The liquid is slowly decomposed when boiled, but more slowly than magnesium sulphide. The sulphides of antimony and arsenic dissolve in the liquid, but not so with the sulphide of mercury. J. Stingl and T. Morawsky prepared magnesium trisulphide, Mg_4S_3 , by the action of magnesium chloride on calcium polysulphide.

F. G. Reichel found that with cold water, amorphous magnesium sulphide furnishes magnesium hydrosulphide, $\text{Mg}(\text{SH})_2$, thus: $2\text{MgS} + 2\text{H}_2\text{O} = \text{Mg}(\text{OH})_2 + \text{Mg}(\text{SH})_2$. According to J. J. Berzelius, and T. J. Pelouze finely divided magnesium hydroxide suspended in water is slowly but abundantly dissolved when hydrogen sulphide is passed through the liquid, and a soln. of magnesium hydrosulphide is formed. A. Béchamp, and L. Naudin and F. de Monthonon, used magnesium carbonate; and E. Divers and T. Shimidzu prepared a soln. by suspending one part of freshly calcined magnesia in not less than ten parts of water. A stream of hydrogen sulphide is passed through the liquid, and the magnesia slowly passes into soln., although much gas passes away unabsorbed. If much more magnesia be added to the water, the resulting soln. of magnesium sulphide is not so conc. as if the proportion of magnesia be less. The soln. can be preserved unchanged by corking the flask and sealing the cork with wax or paraffin to exclude air; when exposed to air, an alkaline liquid is formed which contains magnesium acid carbonate as well as magnesium hydroxide. Magnesium hydrosulphide mixed with an alkali salt is obtained by mixing a soln. of a magnesium salt with an alkali hydrosulphide or barium hydrosulphide. F. Gerhard prepared a similar soln. by mixing magnesium sulphate with sodium sulphide or calcium sulphide; J. Thomsen, and A. Béchamp worked with a soln. of barium hydrosulphide.

J. J. Berzelius, and A. Béchamp, found that the soln. decomposes when an attempt is made to conc. it by evaporation in vacuo or in an atm. of hydrogen; F. G. Reichel found some thiosulphate is formed. Similarly, when the soln. of magnesium hydrosulphide is mixed with a conc. soln. of potassium hydrosulphide, or when a conc. aq. soln. of magnesium chloride is mixed with a conc. soln. of potassium hydrosulphide, hydrogen sulphide is given off. The soln. is also decomposed on boiling. According to E. Divers and T. Shimidzu, when the impurities have settled, the soln. is nearly colourless, and the slight yellow coloration is due to polysulphide formed by the action of ferric oxide in the magnesia, or of air. The polysulphide is decomposed by hydrogen sulphide and sulphur when the products are magnesium hydrosulphide and sulphur; and it is but slightly decomposed by boiling the liquid when the products are magnesium hydroxide, sulphur, and hydrogen sulphide. At 12° , a soln. of magnesium hydrosulphide with 16.31 per cent. of $\text{Mg}(\text{SH})_2$ has a sp. gr. 1.118; the aq. soln., at 60° , develops a steady stream of hydrogen sulphide, and magnesium hydroxide is precipitated, and the evolution of gas can be maintained for a considerable time longer by raising the temp. to 90° – 100° . This is recommended by them as a source of arsenic-free hydrogen sulphide. The aq. soln. oxidizes on exposure to air, forming thiosulphate and polysulphide. "If the soln. be left at rest, oxidation is much impeded by the formation of a firm colourless transparent amorphous film on the surface of the liquid, consisting apparently of magnesium hydroxide, but possibly of *magnesium hydroxyhydrosulphide*, $\text{Mg}(\text{OH})\text{SH}$. The soln. does not readily, if at all, absorb carbon dioxide from the atm. in the early stages of its decomposition." Magnesium hydrosulphide is readily decomposed by an acid giving off hydrogen sulphide. A soln. of magnesium hydrosulphide dissolves antimonious or mercuric sulphide, forming

thiosalts. J. Thomsen found for the heat of formation, $(\text{Mg}, 2\text{S}, \text{H}_2)\text{aq.} = 114.88$ Cals., and $(\text{MgO}_{\text{aq.}}, 2\text{H}_2\text{S}_{\text{aq.}}) = 15.68$ Cals.

§ 12. Magnesium Sulphates

Magnesium sulphate occurs in nature in rhombic crystals of *kieserite* or *reichardtite*, which is the monohydrated sulphate, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$. The mineral may be massive, compact, or granular. Early analyses were made by C. F. Rammelsberg, M. Siewert, B. Leopold, L. N. Vauquelin, and E. Reichardt.¹ It occurs in the Stassfurt salt-mines in beds 9–12 ft. thick with alternating layers of sodium chloride; and it is often mixed with carnallite and gypsum. Magnesium sulphate also occurs in rhombic crystals as *Epsom salts*, or *epsomite*, which is the heptahydrated sulphate, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$. Heptahydrated magnesium sulphate has received many other names: *Seidlitz salt*, *sal amarum*, *sal anglicum*, *sal catharticum*, *Seidschütz salt*, *bitter salts*, etc. The mineral appears as a delicate fibrous scum or efflorescence on walls, and rocks; and in the galleries of mines and caves; it has been reported in gypsum mines, limestone caves, and on dolomites, serpentines, etc. W. H. Emory² reported it in the Californian plains, east of San Diego. Magnesium sulphate is also found in many mineral waters and springs, and in the bittern of sea-water. Analyses have been made by J. Bouis, A. Dufrenoy, F. Stromeyer and J. F. L. Hausmann, etc. It also occurs combined with calcium, sodium, and potassium sulphates as complex or double salts (*q.v.*).

Crude salts are mined, and shipped as a commercial grade, or the salts may be refined by crystallization. Magnesium sulphate obtained by crystallization from aq. soln. is usually in the form of epsomite, *i.e.* the heptahydrate; and it is conveniently made by dissolving the oxide, hydroxide, or carbonate in sulphuric acid, and evaporating the soln. to crystallization. The purified carbonate or hydroxide can be obtained from the purified chloride, *q.v.* It is doubtful if crystals of the anhydrous sulphate have been made. According to T. Graham,³ anhydrous magnesium sulphate, MgSO_4 , is obtained by heating the hydrated salt "to an incipient red heat for a considerable time." Incipient red heat is certainly over 500°. Hence, from G. H. Bailey's observations some oxide is probably formed as well. C. Schmidt made the anhydrous sulphate by warming the heptahydrate to 200°. H. G. F. Schröder found all the water is expelled from the hydrated salt in vacuo at 180°.

Magnesium sulphate has been obtained by evaporation from mineral waters and salt springs; or as a by-product from the mother liquid remaining after the evaporation of sea-water in making sea-salt. F. Michels⁴ prepared it from the kieserite remaining after the extraction of potassium chloride from the Stassfurt Abraumsalzen. E. F. Anthon obtained it as a by-product in the preparation of carbon dioxide by the action of sulphuric acid on magnesite. J. H. Swindells treated dolomite with sulphuric acid, but found much

acid was expended in converting the calcium carbonate into sulphate; and F. Findeisen proposed to remove the lime by washing calcined dolomite with water—*vide* the decalcification of dolomite. The impurities in commercial magnesium sulphate have been discussed by W. L. Kölreuter,⁵ J. S. F. Pagenstecher, and by E. Biltz, and E. Merck.

The hydrates of magnesium sulphate.—Hydrates of magnesium sulphate, $\text{MgSO}_4 \cdot n\text{H}_2\text{O}$, have been reported, with $n=1, 1\frac{1}{2}, 2, 4, 5, 6, 7$, and 12. The hexa- and hepta-hydrates have each two different crystalline forms. The mineral *kieserite* occurring in the Stassfurt salt-beds, Hallstadt, etc., and named after M. Kieser, of Jena, is the native form of **monohydrated magnesium sulphate**, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$. This is a light grey, fine-grained mass which has been analysed by C. F. Rammelsberg,⁶ E. Reichardt, J. Bräuning, etc. According to H. Grüneberg, the grains are often cemented together with sodium chloride, which can be removed by washing. L. Playfair and J. P. Joule made the monohydrate by heating the heptahydrate to $130^\circ\text{--}140^\circ$. According to J. H. van't Hoff, W. Meyerhoffer, and N. Smith, it is formed by heating the heptahydrate to 132° ; its temp. of formation from the hexahydrate is between 67° and 68° , so that the intermediate hydrates can be formed only by slowing down the speed of the transformation. Well-formed crystals are not common; but it does occur as octahedral crystals. According to G. Tschermak, the crystals do not lose their water at 100° , and when heated to a higher temp., they fly to pieces without melting. G. Clemm found that the crystals dissolve unchanged in cold water, and that the solubility does not exceed that of gypsum. The solubility curve is indicated in connection with Fig. 22. When kept in moist air, E. Reichardt found that the crystals become opaque, take up a mol of water, and set like a cement; while F. Bischof said that under water, the crystals likewise set to a cement-like mass which dissolves in warm water as the heptahydrate. According to H. Grüneberg, when the crystals are calcined—presumably the anhydrous salt is formed—the powdered mass readily dissolves in hot water. T. Graham showed that the odd mol of water is not expelled from the monohydrate at $210^\circ\text{--}238^\circ$, and he applied the term *water of constitution* or *water of halhydration* to this mol of water to distinguish it from the water of crystallization. S. U. Pickering said that the gist of this theory is that the so-called constitutional water is not *water* at all, but hydrogen and oxygen, forming part of the salt nucleus itself; crystallized magnesium sulphate is not the heptahydrate of $\text{SO}_2(\text{MgO}_2)$ but the hexahydrate of $\text{SO}(\text{MgO}_2)(\text{HO})_2$, that this latter salt (improperly regarded as a monohydrate, $\text{SO}_2(\text{MgO}_2) \cdot \text{H}_2\text{O}$, is an “atomic” compound decomposable by heat into $\text{SO}_2(\text{MgO}_2) + \text{H}_2\text{O}$, just as monosodium phosphate, $\text{PO}(\text{NaO})(\text{HO})_2$, is decomposed by the same agent into a totally different salt, $\text{PO}_2(\text{NaO})$ and H_2O . He further argued that we have no grounds for supposing that the various water mols. in a hydrated salt are not all combined in a similar manner, and do not all occupy exactly the same position with regard to the salt nucleus; that, in short, a hydrated salt is not a symmetrical substance. At the same time, it must be admitted that we have no positive evidence to show that it is symmetrical. E. Erlenmeyer represented the formula of magnesium sulphate with a molecule of T. Graham's water of halhydration, by HO.Mg.HSO_4 .

Analyses by C. F. Rammelsberg, and by E. Reichardt point to the possible existence of a hydrate intermediate between the mono- and di-hydrates; N. A. E. Millon also obtained a hydrate which he regarded as $\text{MgSO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, by heating a higher hydrate to $110^\circ\text{--}115^\circ$ while the monohydrate is formed at 140° to 180° ; J. H. van't Hoff and H. M. Dawson showed that the composition more probably corresponds with **pentatetritahydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 1\frac{1}{4}\text{H}_2\text{O}$, and that it is best obtained by keeping the soln. used for the preparation of the tetrahydrate, or by evaporating that soln., at a rather higher temp. than is employed for the last-named salt. These temp. are above the transition temp. for the change $\text{MgSO}_4 \cdot 4\text{H}_2\text{O} \rightarrow \text{MgSO}_4 \cdot 1\frac{1}{4}\text{H}_2\text{O}$, which is nearly 20° , but at 20° the evaporation must be very slow to produce the pentatetritahydrate. This salt crystallizes more readily than the dihydrate from which it is readily obtained,

in the presence of magnesium chloride, by evaporation at 65°. The crystals of this hydrate are quite different from those of kieserite.

L. Playfair prepared **dihydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 2\text{H}_2\text{O}$, by boiling the finely powdered heptahydrate with absolute alcohol, and also by heating the heptahydrate to 100°. Observations by N. A. E. Millon pointed to the existence of a dihydrated magnesium sulphate. J. H. van't Hoff and H. M. Dawson found that this salt is not obtained by keeping at 25° the soln. containing magnesium chloride from which the tetrahydrate is produced, but is formed by evaporating the soln. at a higher temp. when a white, badly crystallizing mass is formed along with the crystals of the tetrahydrate. The transition temp. $\text{MgSO}_4 \cdot 4\text{H}_2\text{O} \rightarrow \text{MgSO}_4 \cdot 2\text{H}_2\text{O}$ is approximately 25°, and the change, at this temp., can be observed under the microscope. J. B. Hannay obtained evidence of the formation of this compound from the dehydration curve of the higher hydrates; and J. Thomsen from the heats of hydration.

According to J. H. van't Hoff and T. Estreicher-Rozbiersky, when a soln. of magnesium sulphate and chloride is evaporated over sulphuric acid at 25°, crystals of the hepta- and hexa-hydrates first separate, then follow crystals of **pentahydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 5\text{H}_2\text{O}$, and later still, six-sided plates of **tetrahydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 4\text{H}_2\text{O}$, appear. The crystals of the two last-named salts are unstable. L. Playfair, and T. E. Thorpe and J. I. Watts claimed to have made the pentahydrate by drying the heptahydrate over sulphuric acid until it ceased to lose weight. J. H. van't Hoff, W. Meyerhoffer, and N. Smith found the transition temp. $\text{MgSO}_4 \cdot 5\text{H}_2\text{O} \rightarrow \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$, to be 77·5°; and nearly the same temp. for $\text{MgSO}_4 \cdot 6\text{H}_2\text{O} \rightarrow \text{MgSO}_4 \cdot 5\text{H}_2\text{O}$.

W. Haidinger, and H. Löwel observed monoclinic crystals of **α -hexahydrated magnesium sulphate**, $\alpha\text{-MgSO}_4 \cdot 6\text{H}_2\text{O}$, resembling those of borax, by evaporating an aq. soln. of magnesium sulphate until a skin is formed, and then keeping the soln. for a long time at 25° to 30°. J. C. G. de Marignac recommended draining the crystals, and drying them at 100°. According to E. Mitscherlich, the crystals of the heptahydrate at 52° rapidly lose one-seventh of their water, and form an aggregate of small prisms. H. Löwel observed that when a soln., prepared by dissolving 200 to 225 parts of the heptahydrate in 100 parts of water, is allowed to stand for some time in a closed vessel, monoclinic crystals of the hexahydrate, or hexagonal crystals of the heptahydrate, may be formed; if the temp. is between 14° and 21°, the crystals form slowly and appear as long prisms; if the temp. be lower than this, the crystals form rapidly and appear as small needles. According to L. de Boisbaudran, tetragonal pyramidal crystals of **β -hexahydrated magnesium sulphate**, $\beta\text{-MgSO}_4 \cdot 6\text{H}_2\text{O}$, are produced by seeding a conc. soln. of magnesium sulphate with tetragonal crystals of nickel cupric sulphate or zinc cupric sulphate. The crystals are unstable and readily pass into the α -form. E. Wiedemann found that at about 50°, the heptahydrate passes into a labile or β -hexahydrate; J. K. van der Heide placed the temp. at 48·2°, and later, 47·2°. In the presence of potassium sulphate, E. Wiedemann found that the labile β -hexahydrate passed into the stable α -form at 90°; or, according to J. K. van der Heide, at 88·5°.

The crystallization of an aq. soln. of magnesium sulphate below 25° furnishes the ordinary or rhombic crystals of **α -heptahydrated magnesium sulphate**, $\alpha\text{-MgSO}_4 \cdot 7\text{H}_2\text{O}$. This salt is represented in nature by the mineral *epsomite*. According to H. Löwel, a second form: **β -heptahydrated magnesium sulphate**, $\beta\text{-MgSO}_4 \cdot 7\text{H}_2\text{O}$, appears in monoclinic crystals when a supersaturated aq. soln. of 200 to 225 grms. of heptahydrated magnesium sulphate is kept between 14° and 21° for some time; and L. de Boisbaudran obtained the β -heptahydrate by seeding a rather more dil. soln. with a crystal of cupric or ferrous sulphate. E. Jänecke found the heptahydrate is in equilibrium with the hexahydrate at 51°. S. Takegami obtained **octohydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 8\text{H}_2\text{O}$, and he gave for the transition points:

J. Fritzsche prepared crystals of **dodecahydrated magnesium sulphate**, $\text{MgSO}_4 \cdot 12\text{H}_2\text{O}$, by freezing a sat. soln. of magnesium sulphate below 0° , and slowly thawing out the ice at 0° . The crystals are opaque when prepared on a small scale, but transparent if prepared on a large scale. Above 0° , they give off water and are converted into opaque crystals of the heptahydrate, without changing their form.

The solubility of magnesium sulphate.—Some idea of the relationship between most of the different hydrates of magnesium sulphate can be gathered from the solubility curve, Fig. 22. Early determinations were made by J. L. Gay Lussac,⁷ E. Tobler, E. Diacon, G. J. Mulder, C. von Hauer, and A. Gérardin. The first named represented his results at 0° , by the solubility curve $S=25.76+0.47816\theta$, but A. Etard showed that between 0° and 123° $S=20.5+0.2276\theta$ gives better results, and between 123° and 190° , $S=48.5-0.4403\theta$. The best representative values, compiled by R. Kremann for the stable binary system $\text{MgSO}_4\text{--H}_2\text{O}$, are illustrated by the continuous curve *ABCDEL*M, Fig. 22. The ice-line, *AB*, by F. Rüdorff, and L. C. de Coppet, corresponds with a percentage solubility, according to L. C. de Coppet, of 13.9 per cent. MgSO_4 at -2.9° , and, according to J. H. van't Hoff, W. Meyerhoffer, and N. Smith, with a eutectic at -3.9° and 19 per cent. MgSO_4 , *B*. The solubility curve *BC* refers to systems with the dodecahydrate, $\text{MgSO}_4 \cdot 12\text{H}_2\text{O}$, at 1.8° and 21.1 per cent. MgSO_4 . At the transition point *C*, 1.8° , both the dodeca- and the rhombic hepta-hydrates are in equilibrium. The solubility curve *CD* refers to systems with the rhombic heptahydrate as solid phase; at the transition point *D*, by J. K. van der Heide, 48° and 33 per cent. MgSO_4 , both the rhombic

FIG. 22.—Solubility Curves of Magnesium Sulphate.

heptahydrate and the hexahydrate are in equilibrium as solid phases. J. K. van der Heide gave $48^\circ\text{--}48.5^\circ$ for the transition point of the hepta- to the hexahydrate; and C. D. Carpenter and E. R. Jette gave 48.4° . The curve *DE* represents the solubility of hexahydrated magnesium sulphate where *E*, according to J. H. van't Hoff, W. Meyerhoffer, and N. Smith, represents the transition point—at 68° and 37 per cent. of magnesium sulphate—between the hexa- and mono-hydrates. The solubility curve *ELM* refers to the monohydrate. The percentage solubilities at the intermediate points are :

MgSO_4		10°	20°	30°	40°	50°	60°	80°	99.4°	164°	188°
	.	23.6	26.2	29.0	31.3	33.5	35.5	38.6	40.6	29.3	20.3
		$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$				$\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$		$\text{MgSO}_4 \cdot \text{H}_2\text{O}$			

where *CD* is compiled from data by H. Löwel, E. E. Basch, and G. J. Mulder; for *DE*, from G. J. Mulder; for *EL*, from A. Geiger; and for *LM*, from A. Etard. Metastable systems are represented by the continuation of the ice-line *BG* to -8.4° , a compound, according to L. C. de Coppet, with 23.6 per cent. of magnesium sulphate, and *G*, according to F. Guthrie, with the eutectic between rhombic heptahydrate and ice, at -5.0° , and 19 per cent. MgSO_4 . The curve *CG* by H. Löwel represents the rhombic heptahydrate which has 20.6 per cent. MgSO_4 at 0° . The dotted curve *PK* by H. Löwel represents the solubility of the hexagonal heptahydrate with solubilities at 0° , 10° , and 20° of 25.8, 27.9, and 30.0 per cent. MgSO_4 .

respectively. The dotted curves *NK*, *KD*, and *EO*, by G. J. Mulder, represent the percentage solubilities of the hexahydrate :

	0°	10°	20°	30°	70°	80°	90°	100°
$\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$	29.0	29.7	30.8	31.2	37.3	39.1	40.8	42.5

By cooling a hot soln. of conc. *sulphuric acid* sat. with anhydrous magnesium sulphate, H. Schiff obtained a syrupy liquid which furnished six-sided plates of **magnesium hydrotetrasulphate**, $\text{MgSO}_4 \cdot 3\text{H}_2\text{SO}_4$; and C. Schultz obtained crystals of **magnesium hydrodisulphate**, $\text{MgSO}_4 \cdot \text{H}_2\text{SO}_4$, or $\text{Mg}(\text{HSO}_4)_2$, under similar conditions. J. Kendall and A. W. Davidson found the solubility of normal magnesium sulphate in sulphuric acid does not exceed 1.4 molar per cent. even on boiling. The sat. temp. of soln., with the solid phase $\text{MgSO}_4 \cdot 3\text{H}_2\text{SO}_4$, were :

Per cent. MgSO_4	0.18	0.32	0.62	0.77	1.07	1.18	1.37
Sat. temp.	25.7°	44.2°	66.0°	72.3°	82.8°	86.7°	91.7°

The salt was not completely dissolved with 1.53 per cent. MgSO_4 . H. Haushofer found the crystals are hexagonal plates too deliquescent to be satisfactorily measured crystallographically. G. Tammann found the salt to be completely decomposed when the soln. is diluted. C. Schultz also found that boiling conc. sulphuric acid dissolves about 2 per cent. of anhydrous magnesium sulphate, and the cooling soln. deposits crystals of **magnesium hexahydrotetrasulphate**, $\text{Mg}(\text{HSO}_4)_2 \cdot 2\text{H}_2\text{SO}_4$, or $\text{MgH}_6(\text{SO}_4)_4$, which K. Haushofer believed to belong to the monoclinic system.

J. B. Richter stated that magnesium sulphate dissolves much more rapidly and abundantly in dil. *hydrochloric acid* than in water, and a clear syrupy liquid is formed. According to F. Margueritte, no precipitation occurs when hydrogen chloride is passed into an aq. soln. of magnesium sulphate; and, according to R. Schiff, no acid salt is formed. According to R. J. Kane, magnesium sulphate is not decomposed by hydrochloric acid, for it can be crystallized unchanged from its soln. in this acid. S. Setschenoff studied the absorption of *carbon dioxide* by soln. of magnesium sulphate. O. Aschan found 100 grms. of 95 per cent. *formic acid*, at 19°, dissolve 0.34 grm. of MgSO_4 . According to C. Hensgen, anhydrous magnesium sulphate is but very sparingly soluble in conc. hydrochloric acid, and the hydrated salt dissolves therein only because its water of crystallization dilutes the acid. Hence it appears that, in the action of hydrogen chloride on the hydrated salt, the gas is at first absorbed by the water of crystallization, forming a liquid in which the anhydrous salt is soluble, but as the hydrochloric acid thus formed becomes more conc. the anhydrous sulphate is gradually deposited.

According to C. J. B. Karsten, a conc. soln. of *sodium chloride* dissolves heptahydrated magnesium sulphate without separating the former salt, but conversely, if sodium chloride be dissolved in a conc. soln. of magnesium sulphate, the last-named salt separates out. The crystallization of a soln. of the two salts re-deposits both salts in crystals without alteration, but T. F. von Grotthus found that if the residue be pulverized and boiled in alcohol, a little magnesium chloride is dissolved; consequently, as stated by C. J. B. Karsten, the products are : magnesium chloride and sodium sulphate as well as the original salts. C. W. Scheele showed that above 0°, there is very little change, but below that temp. decahydrated sodium sulphate crystallizes out and magnesium chloride remains in soln. According to J. J. Berzelius, if a soln. of 2 parts of heptahydrated magnesium sulphate and one part of sodium chloride be dissolved in 4.5 parts of water; evaporated a little; and then cooled to -3°, decahydrated sodium sulphate is precipitated and magnesium chloride remains in soln. If the mixture be gently warmed the original salts are reproduced, but above 50°, added H. Rose, the soln. deposits anhydrous sodium sulphate. C. J. B. Karsten stated that an aq. soln. of magnesium sulphate is decomposed by double affinity when mixed with *ammonium chloride*, *potassium chloride*, or *potassium nitrate*, and the alkali sulphate so produced unites with the undecomposed magnesium salt to form a double sulphate. F. Pfaff found a sat.

soln. contains 13.09 parts of *sodium sulphate* and 15.31 parts of *magnesium sulphate* per 100 parts of water at 0°; and E. Diacon further found that 100 grms. of water dissolve at

	17.9°	24.1°	30°	33°	36°	40°
Na ₂ SO ₄ .	16.70	25.70	29.73	27.82	26.29	24.01
MgSO ₄ .	30.41	31.01	28.92	24.87	26.59	30.89

C. J. B. Karsten and others have also discussed this subject in connection with the double salts of *magnesium sulphate* with *sodium* or *potassium sulphate*. C. J. B. Karsten found *heptahydrated magnesium sulphate* dissolves rapidly and without precipitation in a conc. soln. of *potassium nitrate*, but when *potassium nitrate* is slowly dissolved in a conc. soln. of *magnesium sulphate*, *potassium sulphate* is precipitated. The *heptahydrate* dissolves in a conc. soln. of *sodium nitrate* without precipitation, but only a little *sodium nitrate* can be dissolved in a conc. soln. of the *heptahydrate* without the soln. becoming turbid owing to the separation of *magnesium sulphate*. H. Precht and B. Wittgen, C. J. B. Karsten, G. J. Mulder, E. Tobler, H. Schiff, and H. Schwarz made observations on the solubility of *magnesium sulphate* in soln. of *potassium sulphate*. H. S. van Klooster measured the percentage solubility (grams of salt in 100 grms. of sat. soln.) of *magnesium sulphate* in aq. soln. of *potassium sulphate*, and found :

MgSO ₄ .	26.76	26.57	26.39	16.36	13.26	12.68	10.69	4.00	0
K ₂ SO ₄ .	0	2.34	4.02	8.43	10.34	10.70	10.84	11.03	10.77
Solid phases	MgSO ₄ ·7H ₂ O			MgSO ₄ ·K ₂ SO ₄ ·6H ₂ O			K ₂ SO ₄		

According to C. J. B. Karsten, an aq. soln. of *magnesium sulphate* dissolves some **calcium hydroxide** from which *calcium sulphate* and *magnesium hydroxide* separate when the soln. is dil., and a basic *magnesium sulphate* if the soln. is conc. According to H. Grüneberg, a mixture of 2 mols of *kieserite*, and one of *calcium hydroxide* made into a slip with water, sets to a hardness with the evolution of heat; if the mixture be calcined and powdered, and again mixed with water, a marble-like mass is formed. C. J. B. Karsten found a soln. of *magnesium sulphate* dissolves a little **calcium sulphate**, while J. H. Dröze found that a conc. soln. of *magnesium sulphate* dissolves no *calcium sulphate*, and *gypsum* is precipitated from its aq. soln. by adding some *heptahydrated magnesium sulphate*; according to R. Fassbender, the precipitate contains 15 per cent. of *magnesium sulphate* and has a crystalline form different from *gypsum*. T. S. Hunt and F. Hoppe-Seyler have studied the action of **calcium carbonate** on soln. of *magnesium sulphate*.

According to H. Schiff, aq. soln. containing 10, 20, and 40 per cent. of *ethyl alcohol* dissolve respectively 64.7, 27.1, and 1.65 per cent. of *heptahydrated magnesium sulphate* at 10°. At higher temp., said A. Gérardin, the solubility increases proportionally with the temp. C. A. L. de Bruyn found that 100 grms. of absolute *ethyl alcohol*, at 3°, dissolved 13 grms. of the *heptahydrate*, and 100 grms. of absolute *methyl alcohol*, at 18°, dissolved 1.18 grms. of anhydrous *magnesium sulphate*, 41 grms. of the *heptahydrate* at 17°, and 29 grms. of the *heptahydrate* at 3° to 4°; while 100 grms. of 93 per cent. *methyl alcohol* dissolved 9.7 grms. of the *heptahydrate* at 17°, and 100 grms. of 50 per cent. *methyl alcohol* dissolved 4.1 grms. of the *heptahydrate* at 3° to 4°. According to W. Eidmann, *magnesium sulphate* is insoluble in *acetone*, and J. F. Snell found that with *acetone* and water, the soln. separates into layers with certain concentrations. J. Timmermans studied the ternary system *phenol*, *magnesium sulphate*, and water. A. Köhler found 100 grms. of a sat. soln. at 31.25° contained 46.52 grms. of *sugar* and 14 grms. of *magnesium sulphate*; 100 grms. of water dissolve 119.6 grms. of *sugar* and 36 grms. of *magnesium sulphate*.

The physical properties of magnesium sulphate.—The crystals of monohydrated *magnesium sulphate* were found by G. Tschermak⁸ to be monoclinic pyramids with axial ratios $a : b : c = 0.9147 : 1 : 1.7455$, and $\beta = 91^\circ 7'$. G. Wyruboff found the crystals of the *tetrahydrate* to be monoclinic prisms, with $a : b : c$

$=0.450:1:?$, and $\beta=90^\circ 11'$; while the pentahydrate forms triclinic pinacoids, with $a:b:c=0.6021:1:0.5605$, and $\alpha=81^\circ 30'$, $\beta=109^\circ 0'$, and $\gamma=104^\circ 55'$. L. de Boisbaudran found the crystals of $\beta\text{-MgSO}_4 \cdot 6\text{H}_2\text{O}$ to be tetragonal pyramids; and those of $\alpha\text{-MgSO}_4 \cdot 6\text{H}_2\text{O}$ were found by J. C. G. de Marignac to be monoclinic prisms with axial ratios $a:b:c=1.4039:1:1.6683$, and $\beta=98^\circ 34'$. J. C. G. de Marignac regarded the crystals of $\beta\text{-MgSO}_4 \cdot 7\text{H}_2\text{O}$ as trigonal, but H. Kopp supposed them to be monoclinic prisms, and B. Gossner recalculated the measurements and obtained the axial ratios $a:b:c=1.220:1:1.582$, and $\beta=104^\circ 24'$. From H. J. Brooke's measurements it follows that $\alpha\text{-MgSO}_4 \cdot 7\text{H}_2\text{O}$, or epsomite, forms rhombic crystals with axial ratios $a:b:c=0.9901:1:0.5709$. H. Grandinger made observations on this subject. E. Blasius, and J. Grailich have studied the **corrosion figures** of epsomite. The latter salt is the ordinary form of magnesium sulphate; it readily forms supersaturated soln., and, according to J. M. Thomson, the seeding of such soln. with crystals of zinc, nickel, iron (ous), or cobalt sulphate causes crystallization, but this is not the case when the soln. is seeded with crystals of sodium chloride, thiosulphate, or with potassium magnesium sulphate.

The reported numbers for the **specific gravity** of anhydrous magnesium sulphate, MgSO_4 , range from C. J. B. Karsten's 2.6066 ; E. Filhol's 2.628 ; C. Pape's 2.675 (16°); L. Playfair and J. P. Joule's 2.706 ; T. E. Thorpe and J. I. Watts' 2.709 at 15° ; to O. Pettersson's 2.770 at 13.8° and 2.795 at 14° . H. G. F. Schröder gave 2.829 , and if prepared by dehydrating the ordinary salt without fusion, 2.480 . The sp. gr. of monohydrated magnesium sulphate, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$, in the form of kieserite was given by F. Bischof as 2.517 ; and G. Tschermak gave 2.569 . For the artificial salt H. G. F. Schröder gave 2.385 ; L. Playfair and J. P. Joule, 2.478 ; C. Pape, 2.281 at 16° ; O. Pettersson, 2.339 at 14° ; and T. E. Thorpe and J. I. Watts, 2.445 at 15° . For the sp. gr. of dihydrated magnesium sulphate, $\text{MgSO}_4 \cdot 2\text{H}_2\text{O}$, L. Playfair and J. P. Joule gave 2.279 ; and T. E. Thorpe and J. I. Watts, 2.373 at 15° . For the sp. gr. of pentahydrated magnesium sulphate, $\text{MgSO}_4 \cdot 5\text{H}_2\text{O}$, L. Playfair and J. P. Joule gave 1.869 ; G. Wyrouboff, 1.718 ; and T. E. Thorpe and J. I. Watts, 1.869 at 15° . Similarly, for monoclinic hexahydrated magnesium sulphate, $\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$, L. Playfair and J. P. Joule gave 1.751 , and T. E. Thorpe and J. I. Watts, 1.734 at 15° . According to C. R. Schulze, the sp. gr. of the two modifications of the hexahydrate are respectively 1.8981 and 1.6151 . J. W. Retgers gave 1.691 at 16° for the sp. gr. of labile monoclinic heptahydrated magnesium sulphate. A large number of determinations of the sp. gr. of rhombic heptahydrated magnesium sulphate have been made, and the results range from J. D. Forbes' 1.636 at 15.5° to E. Filhol's 1.571 . Other determinations were made by J. H. Hassenfratz, 1.6603 ; H. Kopp, 1.674 ; L. Playfair and J. P. Joule, 1.6829 at 4° ; H. Schiff, 1.685 ; H. J. Buignet, 1.675 ; S. Holker, 1.665 at 15.5° ; C. Pape, 1.701 at 16° ; O. Pettersson, 1.688 ; H. G. F. Schröder, 1.678 ; W. C. Smith, 1.632 ; J. W. Retgers, 1.678 at 16° ; and T. E. Thorpe and J. I. Watts, 1.678 at 15° . G. Krause gave 1.61 to 1.71 for the sp. gr. of reichardite, and 2 to 3 for its **hardness**; the hardness of kieserite is 3 . The **specific volumes** of magnesium sulphate and its hydrates, determined by T. E. Thorpe and J. I. Watts, are:

Hydrate . . .	0	1	$1\frac{1}{2}$	2	4	5	6	7
Mol. wt. . . .	120	138	—	156	—	210	228	246
Sp. vol. . . .	44.8	55.6	—	67.0	—	112.4	130.8	146.6

The mol. vol. of the dissolved magnesium sulphate, calculated from the sp. gr. of the aq. soln., is zero in $0.3N$ -soln., and increases with a rising positive value as the conc. is augmented. L. de Boisbaudran,¹⁰ and J. H. Pollok found a contraction occurs when the heptahydrate crystallizes from a supersaturated soln. According to R. Broom, if a soln. of 30.5 grms. of anhydrous magnesium sulphate in 100 c.c. of water be mixed with an equal volume of water, a percentage contraction 0.677 occurs. E. F. Anthon, A. Michel and L. Krafft, W. W. J. Nicol, H. Schiff, and A. C. Oudemans have measured the sp. gr. of soln. sat. at different temp.

G. T. Gerlach measured the sp. gr. of aq. soln. of magnesium sulphate at 15°, and making a selection from these values,

Per cent. MgSO_4	.	1	.	2	.	5	.	10	.	15	.	20	.	25
Sp. gr.	.	1.01031	.	1.02062	.	1.05154	.	1.10529	.	1.16222	.	1.22212	.	1.28478

H. T. Barnes and A. P. Scott also measured the sp. gr. of soln. with 2.01 to 26.25 per cent. of MgSO_4 at 18.2°; and J. G. McGregor over the range 0.191 to 1.132 per cent. of MgSO_4 at 19.5°. The latter represented his results at 20° by the formula $S = S_t + 0.0106324w$, where w denotes the percentage composition, and S_t the sp. gr. of water; at 23°, the constant is 0.0098176. F. Kohlrausch and W. Hallwachs, O. Pulvermacher, and several others have made more or less subsidiary determinations—e.g., H. C. Jones and F. H. Getman, D. Dijken, J. Forchheimer, O. Schönrock, W. Ostwald, J. Kannonikoff, C. A. Valson, J. Thomsen, S. Charpy, P. Barbier and L. Roux, E. Forster, H. Hager, P. de Heen, A. Sprung, R. J. Holland, H. Sentis, O. Knöfler, etc.

The **viscosity** of aq. soln. of magnesium sulphate has been measured by S. Arrhenius, O. Pulvermacher, W. W. J. Nicol, and J. Wagner. The latter found at 25° for N -, $\frac{1}{2}N$ -, $\frac{1}{4}N$ -, and $\frac{1}{8}N$ -soln., the respective viscosities 1.3673, 1.1639, 1.0784, and 1.0320, when water is unity. H. Sentis, A. Battelli and A. Stefanini, and W. Grabowsky have measured the **surface tension** of soln. of magnesium sulphate. The latter found for the surface tension σ and the capillary constant a^2

Per cent. MgSO_4	.	.	10°			30°		
			10.63	18.83	21.35	10.63	18.83	33.6
a^2 sq. mm.	.	.	13.94	13.21	13.05	13.45	12.79	12.45
σ dynes per cm.	.	.	76.2	78.4	79.3	73.0	75.5	79.2

P. G. Tait found the **compressibility** of 16.06, 10.51, and 6.23 per cent. aq. soln. of magnesium sulphate to be $\beta \times 10^6 = 29.6, 33.5$, and 36.5 respectively. W. Watson also measured this constant. T. Graham experimented on the diffusion of magnesium sulphate in aq. soln. J. D. R. Scheffer measured the **diffusion coefficient**, k , of magnesium sulphate and at 5.5°, found that for soln. with 0.54 and 2.18 mols per litre, k is 0.32 and 0.28 respectively, and at 10° for soln. with 0.40 and 3.23 mols per litre, k is 0.34 and 0.27 respectively; similarly, J. Schuhmeister found that k is 0.28 for a soln. with 1.7 mols per litre at 10°. W. Stiles found that the rate of diffusion in 0.5 per cent. agar-agar is nearly the same as in water; and in 10 per cent. gelatine, the rate is decreased nearly 25 per cent.

S. de Lannoy measured the thermal expansion of soln. of magnesium sulphate, and he found that with 3.796 per cent. of heptahydrated magnesium sulphate, for a temp. θ , between 0° and 40°, $v = v_0(1 - 0.05\theta + 0.06585\theta^2)$; and between 40° and 75°, $v = v_0(1 + 0.04591\theta + 0.05397\theta^2)$; for soln. with 9.915 per cent. of the heptahydrate, between 0° and 40°, $v = v_0(1 + 0.04708\theta + 0.05431\theta^2)$, and between 40° and 85°, $v = v_0(1 + 0.031037\theta + 0.053453\theta^2)$; for soln. with 19.688 per cent. of the heptahydrate, between 0° and 40°, $v = v_0(1 + 0.03139\theta + 0.05335\theta^2)$, and between 40° and 82°, $v = v_0(1 + 0.03162\theta + 0.052775\theta^2)$; while for soln. with 24.437 per cent. of the heptahydrate, between 0° and 82°, $v = v_0(1 + 0.032079\theta + 0.05224\theta^2)$. E. Wiedemann found the thermal expansion up to 50° to be quite regular, when the vol. abruptly increases, owing to the elimination of water by the salt: $\text{MgSO}_4 \cdot 7\text{H}_2\text{O} \rightarrow \text{MgSO}_4 \cdot 6\text{H}_2\text{O} + \text{H}_2\text{O}$, and then expands quite regularly up to 93°; between 93° and 100° there is a marked contraction, and this is subsequently followed by a regular expansion.

According to G. H. Bailey,¹¹ when magnesium sulphate moistened with sulphuric acid is heated to 360°, all the free sulphuric acid is expelled and the weight remains constant up to 450°. R. Reidenbach found the weight of anhydrous magnesium sulphate remains constant from 650° to 700°, but dissociation begins at 750°, and is completed at 850°. G. H. Bailey added that when the sulphate is ignited for the oxide, a trace of sulphuric acid is retained very tenaciously even after a prolonged

ignition. C. Daubeny found that the sulphate lost about a quarter of its contained sulphur trioxide when heated for 3 hrs. at a bright red heat; and he stated that if heated for a still longer time, the cold product gives a residue insoluble in water, and which gives off some hydrogen sulphide when treated with acids. J. B. J. D. Boussingault stated that when small quantities are heated in the blast-flame, all the sulphur trioxide can be expelled. H. le Chatelier stated that the decomposition of the sulphate begins at 1160° . A. S. Ginsberg gave 1120° for the **melting point** (f.p.) of molten magnesium sulphate, and R. Nacken, 1124° . The latter stated that the salt is considerably decomposed at its m.p. According to G. J. Mulder, heptahydrated magnesium sulphate, in dry air for 45 days, loses 8.3 to 9.1 per cent. of water, and its composition remains constant; and, according to T. Graham, if kept at 22° in vacuo, or at 100° in air, rather more water than is required for the dihydrate remains; at about 130° the monohydrate is formed, and the latter loses all its combined water at a higher temp.—*vide* preparation of the anhydrous sulphate. According to G. J. Mulder, the per cent. water which is lost after heating to:

	40°	60°	82°	101°	119°	172°	201°
Water lost . . .	8.7	33.2	34.7	34.7	40.5	40.8	41.5
Mol. eq. . . .	H ₂ O	3.5H ₂ O	—	5H ₂ O	—	—	6H ₂ O

The theoretical loss for the whole of the water in the heptahydrate is 51.2 per cent. H. G. F. Schröder found dehydration was complete in vacuo at 180° ; and V. A. Jacquelin found that the salt which has lost 12.4 per cent. of water in vacuo, regains all the lost water on exposure to air. J. B. Hannay found the dehydration curve of the heptahydrate at 100° has breaks indicating the formation of the dihydrate and of *trihydrated magnesium sulphate*, but there is no other evidence in favour of the individuality of the trihydrate. See the individual hydrates for their temp. of formation.

According to C. Pape,¹² the **specific heat** of solid anhydrous magnesium sulphate is 0.225 between 25° and 100° ; and, according to H. Kopp, the sp. ht. of heptahydrated magnesium sulphate is 0.3615 between 20° and 42° ; C. Pape gave 0.407 for the heptahydrate between 15° and 28° ; and 0.265 for the monohydrate between 25° and 100° . J. C. G. de Marignac found that the sp. ht. of aq. soln. of magnesium sulphate containing n mols of water per mol of MgSO₄, are 0.8690, 0.9230, and 0.9550, when $n=50, 100$, and 200 at 22.52° . G. Tammann measured the sp. ht. of dil. soln.; and other determinations have been made by K. Bindel, S. Pagliani, J. Thomsen, and H. Teudt. G. Jäger found the **thermal conductivity** of a 22 per cent. soln. of magnesium sulphate to be 97.5 when that of water is 100.

E. Cohen,¹³ and P. C. F. Frowein have measured the **vapour pressure** of heptahydrated magnesium sulphate; the former's results above 30.75° , and the latter's results below that temp., are:

	14.95°	25.75°	30.75°	40.04°	41.42°	43.40°	47.45°
Vap. press. . . .	4.93	12.29	18.34	37.90	41.89	43.37	64.31 mm.

P. C. F. Frowein obtained 18.35 mm. for the vap. press. of hexahydrated magnesium chloride at 30.75° . This number is probably low, since E. Cohen obtained 18.96 mm. and H. Bolte 18.92 mm. The vap. press., p , obtained by H. W. Foote and S. R. Scholes; and p' by H. Bolte, are, at 25° ,

	0-H ₂ O	1-4H ₂ O	4-5H ₂ O	5-6H ₂ O	6-7H ₂ O
p mm. . . .	1.0	4.9	8.8	9.8	11.5
p' mm. . . .	—	4.6	7.9	10.1	12.0

For the 6-7 hydrate, P. C. F. Frowein gave 11.5 mm.; H. Lescœur, 11.7 mm.; E. Cohen, 12.0 mm.; W. C. Schumb, 12.50 mm.; and G. Wiedemann, 18.0 mm. at 25° . A. W. C. Menzies showed that there are initial disturbances in the observed results due to the redistribution of absorbed air by the salt and apparatus. H. Lescœur found the vap. press. of a sat. soln. of magnesium

sulphate at 20° to be 5.75 mm. G. Tammann found that with soln. containing 10.43, 25.33, and 50.74 grms. of MgSO_4 in 100 grms. of water, the vap. press. at 100° was lowered respectively 10.8, 26.4, and 82.7 mm.; and with soln. containing 6.33, 26.10, and 48.71 grms. of $\text{Mg}(\text{HSO}_4)_2$ in 100 grms. of water, the vap. press. at 100° was lowered 10.3, 57.0, and 136.1 mm. respectively. Measurements were also made by C. D. Carpenter and E. R. Jette. According to H. C. Jones and F. H. Getman,¹⁴ the molecular **freezing point** lowering has a minimum with 0.48*N*-soln. This has been also studied by T. G. Bedford, H. Hausrath, F. M. Raoult, L. Kahlenberg, E. H. Loomis, S. Arrhenius, and A. A. Noyes and F. G. Falk. From these observations:

Grms. MgSO_4 per 100 grms. H_2O	0.00141	0.02867	0.699	2.534	9.768	18.343
Lowering of f.p.	0.000433°	0.007382°	0.154°	0.469°	1.629°	3.471°
Mol. lowering of f.p.	3.70°	3.10°	2.65°	2.23°	2.01°	2.08°

The **boiling point** of a sat. soln. is 105° , according to T. Griffiths, and G. J. Mulder, 108.4° ; G. T. Gerlach found soln. with 8.8, 39.5 and 75 grms. of MgSO_4 in 100 grms. of water boiled respectively at 100.5° , 103° , and 108° . L. Kahlenberg found the raising of the b.p. of soln. with 2.733, 7.236, 43.47, and 72.28 grms. MgSO_4 per 100 grms. of water was respectively 0.097°, 0.281°, 1.455°, and 3.630°, and the mol. raising of the b.p. respectively 0.43°, 0.47°, 0.403°, and 0.605°.

According to J. Thomsen,¹⁵ the **heat of formation** is (Mg , O , SO_3 , aq.) = 180.18 Cals.; and (Mg , O_2 , SO_2) = 232.31 Cals. M. Berthelot gave (Mg , S , 2O_2) = 309.0 Cals., and he also found for ($\text{Mg}(\text{OH})_2$ precipitated, $\text{H}_2\text{SO}_{4\text{aq}}$) = 31.2 Cals. J. Thomsen's values for the **heat of hydration** with the 1st, 2nd, 3rd, . . . and the 7th mols of water are:

1st	2nd	3rd	4th	5th	6th	7th
6.98	2.25	3.60	3.21	2.23	2.11	3.70 Cals.

F. Rüdorff found the temp. fell from 19.1° to 3.1° on mixing 85 parts of the heptahydrate with 100 parts of water. T. Graham concluded from his observations on the heat disengaged in the combination of dehydrated magnesium sulphate with water that "of the whole heat evolved in the complete hydration of magnesium sulphate, as nearly as possible one-fourth is due to the combination of the first mol. of water." S. U. Pickering's values for the **heat of solution** in 420 mols of water per mol MgSO_4 , at 22.2° , are 20.765 Cals. for the anhydrous salt, 12.131 Cals. for the monohydrate, and -3.86 to -3.915 Cals. for the heptahydrate. J. Thomsen found for the heat of soln. in 400 mols of water per mol of the sulphate:

$n\text{H}_2\text{O}$:	:	:	0	1	2	3	4	5	6	7
Cals.	:	:	:	20.28	13.30	11.05	7.45	4.24	2.01	-0.10	-3.80

M. Berthelot and L. Ilosvay de N. Ilosva represent the heat of soln. of the anhydrous sulphate in water at θ° by $20000 + 0.00007(\theta - 15)$. C. M. van Deventer and H. J. van de Stadt give -4.1 Cals. for the integral heat of soln.

According to G. Tschermak,¹⁶ the monohydrated sulphate has a positive **double refraction**; so also, according to G. Wyruboff, has the tetrahydrate, while the pentahydrate and the hexahydrate have a negative double refraction; and, according to A. des Cloizeaux, the rhombic heptahydrate has also a negative double refraction. The **indices of refraction** of crystals of heptahydrated magnesium sulphate for the *D*-line have been determined by F. Kohlrausch, H. Dufet, and A. Fock, while H. Töpsöe and C. Christiansen found:

		μ_x	μ_β	μ_γ
F-line	.	1.4374	1.4607	1.4657
D-line	.	1.4325	1.4554	1.4608
C-line	.	1.4305	1.4530	1.4583

C. Borel also made determinations over the range $\lambda = 226$ to $\lambda = 718$. The index of refraction of soln. of magnesium sulphate has been measured by W. Hallwachs,

O. Pulvermacher, B. Wagner, J. Dinkhauser, and D. Dijken. The sp. refractive power of the solid salt (calculated from measurements on soln.) was found by E. Forster to be 0.2102 at 24°. P. Barbier and L. Roux measured the dispersion of soln., and D. Dijken, the mol. refraction and dispersion. According to J. Forchheimer, the **magnetic rotatory power**, or the specific electromagnetic **rotation of the plane of polarization** of 0.934*N*-, 1.86*N*-, and 2.73*N*-soln. is 0.306, 0.313, and 0.305 respectively, and the mol. electromagnetic rotation of the plane of polarization, 2.04, 2.02, and 2.03 respectively. This constant is therefore independent of conc. O. Schönrock gave 0.2978 for the specific rotation and 1.986 for the mol. rotation. L. Longchambon found the rotatory power of heptahydrated magnesium sulphate is 19° 15' for both axes. According to P. Bary, anhydrous magnesium sulphate does not fluoresce on exposure to **X-rays** or to **Becquerel's rays**.

The **electrical conductivity** of molten magnesium sulphate and of mixtures with potassium sulphate has been measured by A. Benrath and K. Drekopf¹⁷; the electrical conductivity of aq. soln. of magnesium sulphate has been measured by W. C. D. Whetham, E. Klein, etc. P. Walden found the conductivity, λ , for an eq. of the salt in v litres to be:

v	.	.	.	32	64	128	256	512	1024
λ	:	:	:	73.0	83.0	92.6	101.8	110.1	116.9

H. C. Jones also measured the mol. conductivity, μ , and calculated the percentage **degree of ionization** α , and the **temperature coefficient**, k , of the mol. conductivity between 0° and 10°; he found at 0°:

v	.	.	.	2	8	16	32	128	512	1024	2048
μ	:	:	:	32.12	45.70	50.95	59.57	71.17	95.57	102.7	111.1
α	:	:	:	28.9	41.1	45.9	53.6	64.1	86.0	92.4	100.0
k	:	:	:	1.10	1.52	1.71	2.01	2.42	3.27	3.57	3.74

Analogous results were obtained at 10°, 25°, 35°, 50°, and 65°. J. Kendall and co-workers measured the conductivity of soln. in anhydrous sulphuric acid. G. N. Lewis and G. A. Linhart measured the **degree of ionization** of dil. soln. of magnesium sulphate; and G. N. Lewis and M. Randall, the activity coeff. of the ions. The **transport numbers** of the ions have been studied by W. Hittorf, A. Chassy, B. D. Steele, W. Bein, K. Hopfgartner, R. B. Denison, and O. Masson. C. Heim found no sudden change in the electrical conductivity on passing from a state of supersaturation to a state of ordinary soln. According to C. Borel,¹⁸ the **dielectric constants** k_1 , k_2 , and k_3 of epsomite are respectively 8.28, 6.05, and 5.26; A. de Gramont studied the **pyroelectricity** of epsomite. J. Grailich and V. von Lang found that the crystals are feebly diamagnetic. The **magnetic susceptibility** of anhydrous magnesium sulphate at 18° and 19° was found by G. Quincke, and S. Meyer to be -0.36×10^{-6} units; C. K. Studley gave -0.46×10^{-6} , and G. Meslin, -0.62×10^{-6} ; for the heptahydrated salt, S. Meyer gave -0.36×10^{-6} . P. Pascal gave 1357×10^{-7} units for the mol coeff. of magnetization.

The chemical properties of magnesium sulphate.—J. B. Richter¹⁹ first noted the evolution of heat which occurs when magnesium sulphate, after ignition, is mixed with **water**; and H. von Blücher noticed that the ignited salt gradually absorbed the eq. of 7H₂O from the air. When the sulphate is heated in a current of steam, G. Clemm noted that the sulphur trioxide can be all driven off. C. W. Scheele found “vitriolated magnesia” is but little affected by **hydrofluoric acid**. C. Hensgen found that **hydrogen chloride** begins to act on magnesium sulphate at a temp. approaching redness, and the reaction is not completed at this temp. in 3 hrs. A. B. Prescott found that when a gram of magnesium sulphate is evaporated to dryness with 4.035 grms. of hydrochloric acid containing 1.251 grms. of HCl, 0.003 gm. of magnesium chloride is formed. C. J. B. Karsten stated that magnesium sulphate melts when heated with **sodium chloride**, and this the more readily the greater the proportion of the latter salt; and G. Clemm noted that when a mixture of the two salts is heated in a current of steam, hydrogen chloride

is evolved. V. Merz and W. Weith found that when melted in air with **potassium iodide**, iodine is set free. J. Zawadsky and co-workers obtained magnesia by the reduction of magnesium sulphate with **hydrogen sulphide**. According to J. L. Gay Lussac, when a mixture of anhydrous magnesium sulphate and **carbon** is heated to redness, a mixture of one vol. of carbon dioxide and two vols. of sulphur dioxide is obtained, some sulphur is liberated but no magnesium sulphide is formed; but P. Berthier obtained a trace of the sulphide when the reaction occurs at a white heat. E. Kunheim obtained similar results. E. H. Riesenfeld has studied the reduction, and found that there are concurrent reactions: $2\text{MgSO}_4 + \text{C} = 2\text{MgO} + 2\text{SO}_2 + \text{CO}_2$, and $\text{MgSO}_4 + \text{C} = \text{MgO} + \text{SO}_2 + \text{CO}$. According to K. Stammer, **carbon monoxide** has no action on red-hot magnesium sulphate; but, according to F. G. Reichel, magnesium oxide, carbonyl sulphide, and carbon dioxide are formed; while O. Boudouard obtained magnesia, and carbon and sulphur dioxides; J. Zawadsky and co-workers obtained in addition free sulphur; and, according to E. Jacquemin, in the presence of steam, carbon dioxide and hydrogen sulphide are formed. A recently prepared mixture of hydrated magnesium sulphate and **sodium hydrocarbonate** was found by L. A. Planche to dissolve in water without turbidity, but a similar mixture, after keeping some months, deposits magnesium carbonate. According to A. d'Heureuse, when a mixture of magnesium sulphate and **iron** is heated to redness, a little sulphur dioxide is evolved, and a mixture of magnesium and iron oxides with a little iron sulphide is formed; when **zinc** replaces the iron, a fulmination occurs. When a mixture of 33 grms. of heptahydrated magnesium sulphate, 5.5 to 9 grms. of **sodium hydroxide**, and 100 c.c. of water is heated between 195° and 205° for 31–55 hrs., two-thirds of the magnesium separates as hydroxide, and the remainder forms doubly refracting acicular crystals of **magnesium hydroxy-sulphate**, $6\text{Mg}(\text{OH})_2 \cdot \text{MgSO}_4 \cdot 3\text{H}_2\text{O}$, which are sparingly soluble in cold and hot water, but readily soluble in hydrochloric acid.

Magnesium sulphate is used in tanning leather, in sizing and loading cotton textiles; in weighting silk, paper, and leather; in dyeing; in enamelling industries; in fireproofing; in making paints and soaps; in the manufacture of mineral waters; and medicinally.

§ 13. The Complex and Double Salts of Magnesium Sulphate

At least three double sulphates of sodium and magnesium occur in the Stassfurt salt deposits, namely, *vanthoffite*, $\text{MgSO}_4 \cdot 3\text{Na}_2\text{SO}_4$; *blödit* or *astrakanite*, or *simonyite*, $\text{MgSO}_4 \cdot \text{Na}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$; and *löweite*, $\text{MgSO}_4 \cdot \text{Na}_2\text{SO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. R. Nacken,¹ S. Takegami, and A. S. Ginsberg have studied the equilibrium conditions in the binary system, MgSO_4 — Na_2SO_4 , and the probable results are shown graphically in Fig. 23. The equilibrium is somewhat complicated. The f.p. curve has a eutectic at 44.2 molar per cent. of MgSO_4 , and 670°; and there is a break at 71.3 molar per cent. and 814°. α -Sodium sulphate forms solid soln. containing up to 35.8 mols per cent. MgSO_4 . The compound **disodium trimagnesium tetrasulphate**, $\text{Na}_2\text{SO}_4 \cdot 3\text{MgSO}_4$, melts with decomposition at 814°. Magnesium sulphate does not form solid soln. The existence of the two other compounds, **disodium magnesium disulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$ and **hexasodium magnesium tetrasulphate**, $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$, formed only in the solid state, is also indicated.

FIG. 23.—Freezing-point Curves of the Binary System, Na_2SO_4 — MgSO_4 .

These compounds are identical with anhydrous blödite and vanthoffite respectively, the former existing in α -, β -, and γ -modifications. Sodium sulphate only forms two modifications, the transition point being at 232° . H. le Chatelier placed the maximum at $\text{Na}_2\text{SO}_4 \cdot 2\text{MgSO}_4$, but this is wrong. Some early work on the mutual solubilities of the sodium and magnesium sulphates has been previously indicated.

Crystals of löweite, *i.e.* **pentahemihydrated sodium magnesium disulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, or $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, were found in masses associated with the anhydrite at the Ischl salt mine, Austria; and they were described by W. Haidinger in 1846, and analyzed by K. von Hauer. Löweite occurs in yellowish-white or reddish-white compact masses. J. H. van't Hoff and G. Just prepared this salt by dissolving 10.5 grms. of sodium chloride in a litre of water, and mixing this with a second soln. containing eq. proportions of magnesium and sodium sulphates. The mixed soln. is then slowly evaporated at 55° to 60° , when astrakanite begins to crystallize out. The soln. is then seeded with löweite, the vessel closed, and kept for several days at the same temp. Crystals of löweite appear. According to J. H. van't Hoff and A. O'Farely, astrakanite is transformed into löweite at 71° ; and a soln. which contains eq. proportions of the component salts, at a temp. exceeding 71° first gives astrakanite, which then passes into löweite. The transition temp. is lowered when other salts are present—*e.g.* it is 43° in the presence of a soln. containing 25 grms. of heptahydrated magnesium sulphate, 7 grms. of sodium chloride, 3 grms. of leonite, and one grm. of astrakanite. The optical properties of the crystals show that they belong to the tetragonal system. W. Haidinger found the sp. gr. of löweite to be 2.376 to 2.42; and the hardness $2\frac{1}{2}$ to 3 on Mohs' scale.

Reddish translucent masses of a mineral from the salt mines of Ischl (Austria) were analyzed by J. F. John in 1811, and found to be eq. to **tetrahydrated sodium magnesium sulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$, or $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$. The mineral was called *blödite*, after M. Blöde. G. Rose obtained imperfect crystals from the salt lakes of Astrakan, east of the mouth of the Volga, and he called the mineral *astrakanite*; analyses showed that the two minerals have virtually the same composition. Crystals also occur in the soil near Mendoza, and east of San Juan, and at Stassfurt; and Munos y Luna found prismatic crystals in the dry beds of some Toledo lakes in summer. The salt has also been analyzed by K. von Hauer, A. A. Hayes, G. vom Rath, A. Brezina, etc. G. Tschermak obtained crystals of a mineral, which he called *simonyite*, resembling those of astrakanite, and of the same composition, but unlike the latter, the crystals of simonyite do not effloresce in air; and P. Groth and C. Hintze's blödite, which was unalterable in air, was probably simonyite; they assumed that the efflorescence of ordinary blödite was due to the presence of some efflorescent salt as impurity. H. F. Link regarded the double salt as a hexahydrate.

A. R. Arrott probably prepared tetrahydrated sodium magnesium sulphate in 1844, by evaporating at 50° a soln. containing eq. proportions of the component salts. J. Koppel, H. W. B. Roozeboom, J. H. van't Hoff and W. Meyerhoffer, and C. M. van Deventer and J. H. van't Hoff have studied the conditions under which the double salt is formed in aq. soln. The transition temp. for the reaction: $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O} + \text{MgSO}_4 \cdot 7\text{H}_2\text{O} \rightleftharpoons \text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O} + 13\text{H}_2\text{O}$, is about 21.5° ; and, according to the latter, if finely powdered astrakanite be mixed with water in the proportion represented by this equation, at a temp. below 21.5° , the thin paste soon sets to a dry solid mixture of the two sulphates, but above 21.5° this does not occur. Similarly, a finely powdered mixture of the two hydrated sulphates remains unchanged if kept in a closed flask below 21.5° , but above that temp. astrakanite is formed, and this is evidenced by the appearance of partial fusion produced by the liberated water. A mixture of heptahydrated magnesium sulphate and of decahydrated sodium sulphate melts at 26° . The formation of astrakanite is accelerated if some of the last-named salt be added at the beginning. The transi-

tion point is lowered by sodium chloride such that a mixture of eq. proportions of decahydrated sodium sulphate, heptahydrated magnesium sulphate, and sodium chloride melts at 15°, the system contracts, and monohydrated sodium sulphate separates out; after a time, the vol. increases, and astrakanite is formed. When this point is reached, the reverse reaction occurs below 5°—cf. Fig. 6, 2, 20, 3. The formation of astrakanite by the reaction symbolized: $2\text{MgSO}_4 \cdot 7\text{H}_2\text{O} + 2\text{NaCl} = \text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O} + \text{MgCl}_2 \cdot 6\text{H}_2\text{O} + 4\text{H}_2\text{O}$, was found to occur above 30·6°.

Astrakanite is somewhat deliquescent in a moderately moist atm. J. Murray said the crystals are permanent in air. W. H. Miller found the axial ratios to be $a : b : c = 1.3492 : 1 : 0.6717$, and $\beta = 100^\circ 48' 5''$. This salt is one member of an isomorphous group in which manganese (ous), iron (ous), and zinc replace the magnesium of astrakanite; but it is not isomorphous with potassium-astrakanite. The crystals of astrakanite have a negative double refraction; the sp. gr. is 2.223 to 2.244; and the hardness 2.5 to 3.5 on Mohs' scale. According to J. H. van't Hoff and A. O'Farely, astrakanite passes into löweite at 71°; and, according to J. H. van't Hoff and G. Just, in the presence of sodium chloride, and seeding with vanthoffite and löweite, the transition temp. is lowered to 59°. G. Tschermak found that the crystals lose about three-eighths of their water—i.e. 7.33 per cent. in weight—when heated on a water-bath; but P. Groth and C. Hintze found 8.8 per cent. is lost at 100°, and 10.12 per cent. at 150°; and G. vom Rath found 10.05 per cent. is lost between 100° and 130°; 10.09 per cent. between 130° and 300°; and the remaining 1.16 per cent. at a red heat. E. Reichardt also made observations on the dehydration of astrakanite. G. Tschermak found the dehydrated mass melts to a clear liquid which glows when it begins to freeze. J. H. van't Hoff and A. O'Farely represented the vap. press., p , of astrakanite at a temp. θ , by the expression $\log p = \log p_w - (166.79 - 2.017\theta)/(273 + \theta)$, where p_w represents the vap. press. of water. J. Murray said that the double sulphate is soluble in three times its wt. of water. According to H. W. B. Roozeboom, 100 mols of water hold in sat. soln.:

		22°	24.5°	30°	35°	47°
Astrakanite	(Na_2SO_4)	2.95	3.45	3.60	3.69	3.60 mols
	(MgSO_4)	4.70	3.68	3.60	3.69	3.60 „

If an excess of either component be present, the solubility of astrakanite is lowered a little. According to J. H. van't Hoff and A. O'Farely, the heat of soln. of astrakanite is 1456 Cals. per kgrm. mol, and of löweite, 7998 Cals.; the heat of transformation of löweite to astrakanite is 6542 Cals. per kgrm. mol.

K. Kubierschky deduced indirectly that anhydrous **hexasodium magnesium tetrasulphate**, $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$, or $\text{Na}_6\text{Mg}(\text{SO}_4)_4$, occurs in the salts from Wilhelms-hall in the Magdeburg-Halberstadt salt district, and he gave it the name *vanthoffite*. J. H. van't Hoff found that the salt is produced artificially by heating the crystals of blödite, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, deposited at 22° from a soln. containing equi-mol. proportions of the component sulphates, which when heated to 70° in the mother liquor, lose some of their water, and are transformed into löweite, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, and at a still higher temp. crystals of the anhydrous salt, $\text{Na}_6\text{Mg}(\text{SO}_4)_4$, appear. Among other methods of preparation, J. H. van't Hoff showed that the salt can be made by digesting on a water-bath a mixture of 154 grms. of water, 54 grms. of sodium chloride, 252 grms. of decahydrated sodium chloride, and 103 grms. of heptahydrated magnesium sulphate; the sodium sulphate first deposited gradually gives way to vanthoffite, and when all is transformed, the crystals are collected on a hot-water suction filter, washed first with 50 per cent. and then with absolute alcohol and dried. According to J. H. van't Hoff and G. Just, 46° is the lowest temp. at which vanthoffite is formed from astrakanite and sodium sulphate in a soln. simultaneously saturated with sodium chloride and glaserite. The crystals of vanthoffite resemble those of löweite; their sp. gr. is 2.7; and the hardness of the natural mineral, containing 10 per cent. of sodium chloride, is 3 on Mohs' scale.

C. H. Pfaff² found that magnesium and potassium sulphates unite together,

producing differently formed crystals—thus H. F. Link said that the crystals are long prisms which crumble in air; and C. L. Berthollet, that the crystals are rhombohedral and permanent in air. There are at least three double salts of magnesium and potassium sulphates in the Stassfurt salt deposits, namely, *langbeinite*, $2\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4$; *leonite*, $\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$; and *picromerite* or *schönite*, $\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$. G. J. Mulder, and J. H. van't Hoff and N. Kassatkin prepared **pentahydrated potassium tetramagnesium pentasulphate**, $\text{K}_2\text{SO}_4 \cdot 4\text{MgSO}_4 \cdot 5\text{H}_2\text{O}$, or $\text{K}_2\text{Mg}_4(\text{SO}_4)_5 \cdot 5\text{H}_2\text{O}$; the latter, by warming a mixture of hexahydrated magnesium sulphate with astrakanite at 72° , or by evaporating a soln. containing a mol of potassium sulphate and four mols of magnesium sulphate when needle-like crystals of leonite are first formed. The leonite finally disappears and the whole mass solidifies. Leonite alone does not form this compound. The transition point is given as 72.5° . It is regarded as a double salt of the hydrate $\text{MgSO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$.

The mineral *langbeinite* was so named by S. Zuckerschwerdt from specimens which he found near Halberstadt (Prussian Saxony). It occurs in the polyhalite regions at Wilhelmshall, and accompanies the sylvite at Westeregeln. The analyses agreed with anhydrous **potassium dimagnesium trisulphate**, $2\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4$, or $\text{K}_2\text{Mg}_2(\text{SO}_4)_3$. G. J. Mulder made this compound in 1864; and F. R. Mallet

FIG. 24.—Freezing-point Curves of the Binary System, K_2SO_4 — MgSO_4 .

obtained well-defined crystals by fusing together at a full red heat mol. proportions of the two components. The clear liquid, on cooling, generally intumesces. The best crystals were obtained by pouring the fused salt into a hot nickel crucible, and allowing the mass to cool. A. S. Ginsberg, and R. Nacken have studied the equilibrium conditions in the binary system, K_2SO_4 — MgSO_4 , and the results are shown graphically in Fig. 24.

The two components are completely miscible in the molten state—region I; in region II, mixed crystals are in equilibrium with the melt; and in region VI the mixed crystals are alone stable. The first eutectic at 747 – 750° corresponds with 38 to 40 molar per cent. of MgSO_4 ; the second eutectic at 884° has 78 molar per cent. of MgSO_4 . In regions III

and IV, the melt and langbeinite are coexistent, and in region VII langbeinite is in equilibrium with the mixed crystals of VI. In region V the melt and magnesium sulphate crystals are coexistent; and in region VIII langbeinite and magnesium sulphate are in equilibrium. Mixed crystals of VI are in equilibrium with β - K_2SO_4 in region IX, and, in region X, langbeinite is in equilibrium with β - K_2SO_4 .

According to J. H. van't Hoff, W. Meyerhoffer, and F. G. Cottrell, the salt crystallizes from a soln. of the component salts at 85° , and at a lower temp. in the presence of dehydrating salts like magnesium chloride; they recommended evaporating a boiling soln. of 17 grms. of potassium sulphate, 49 grms. of heptahydrated magnesium sulphate, and 75 grms. of hexahydrated magnesium chloride, until the langbeinite which is formed no longer dissolves, and then further evaporating on a water-bath until magnesium chloride begins to separate. The product is washed with 50 per cent. alcohol, and is then nearly free from chlorides and water. Although the transformation temp. of leonite to langbeinite is 89° , the transformation of leonite to langbeinite is extremely slow at 100° , and requires a temp. of

120°. The temp. of formation of langbeinite from a mixture of leonite and hexahydrated magnesium chloride is 61°. The presence of hexahydrated magnesium sulphate depresses the temp. of formation of langbeinite from leonite, down to 61°; but this temp. may be easily passed without the change taking place, and at 72°, the unstable $K_2Mg_2(SO_4)_5 \cdot 5H_2O$ is formed and readily passes into langbeinite when a little of the latter is present. The presence of sodium chloride lowers the temp. of formation still further.

According to O. Luedecke, crystals from Bernburg belong to the tetartohedral class in the cubic system; the octahedra obtained by F. R. Mallet are therefore supposed to be compounded of two tetrahedrons of opposite sign. The corresponding salts of zinc, manganese, and cobalt have the tetrahedron predominant. According to R. Nacken, the sp. gr. of the artificial salt is 2.829 at 25°; and O. Luedecke gives for the natural crystals 2.827 to 2.830. From the maximum in Fig. 24, the m.p. is 927°. The crystals are singly refracting, and, according to O. Luedecke, the index of refraction is 1.5281 for the Li-line, 1.5329 for the Na-line, and 1.5343 for the Tl-line. The crystals do not rotate the plane of polarization of light. F. R. Mallet observed that the salt gradually absorbs moisture from the atm. and decomposes into picromerite and epsomite: $K_2SO_4 \cdot 2MgSO_4 + 13H_2O = MgSO_4 \cdot K_2SO_4 \cdot 6H_2O + MgSO_4 \cdot 7H_2O$. According to O. Schumann, when the double sulphate of magnesium and potassium is heated in a stream of hydrogen, hydrogen sulphide, sulphur, and water are formed, and a mixture of magnesium oxide and potassium sulphide remains. F. R. Mallet prepared **rubidium dimagnesium trisulphate**, $Rb_2SO_4 \cdot 2MgSO_4$, or $Rb_2Mg_2(SO_4)_3$ —this is *rubidium langbeinite*—in a similar way to that which he employed for langbeinite, and he found that it had similar properties.

No compound of the type *potassium magnesium disulphate*, $K_2SO_4 \cdot MgSO_4$, or $K_2Mg(SO_4)_2$, appears on the thermal diagram, Fig. 24, although M. Berthelot and L. Ilosvay de N. Ilosvay claimed to have made it by fusing the component salts in the right proportions, and F. R. Mallet likewise claimed to have made this compound as well as rubidium magnesium disulphate by a similar process. He also made some measurements on the hygroscopic crystals. L. Playfair and J. P. Joule gave 2.676 for the sp. gr. of the crystals, and H. G. F. Schröder, 2.743.

According to A. Naupert and W. Wense, crystals of **tetrahydrated potassium magnesium disulphate**, $K_2SO_4 \cdot MgSO_4 \cdot 4H_2O$, or $K_2Mg(SO_4)_2 \cdot 4H_2O$, occur in the kainite beds of Westeregeln, and they are readily distinguished from the surrounding kainite; they also occur associated with the blue rock salt. At Leopoldshall, the mineral occurs as thick tabular crystals along with kainite and rock salt. The colour varies from a very pale yellow to a reddish, greyish-yellow. Analyses have been made by A. Naupert and W. Wense, C. A. Tenne, and J. E. Strandmark; the results are in agreement with the formula—the massive variety usually contains chlorides as impurities. This salt was obtained by J. K. van der Heide, by evaporating an aq. soln. of schönite and sodium chloride at 60°, or a soln. of magnesium and potassium sulphates at 100°. He called the salt *potassium astrakanite*, and it has also been called kaliblödite, but C. A. Tenne showed that there is no crystallographic relation between this mineral and blödite or astrakanite, and he therefore prefers the name *leonite*. The monoclinic prisms were found by C. A. Tenne to have axial ratios $a : b : c = 1.03815 : 1 : 1.23349$, and the axial angle $\beta = 84^\circ 50'$. The optical axial angle is perpendicular to the plane of symmetry, and makes an angle $29^\circ 30'$ with the base. There is no distinct cleavage, and the fracture is conchoidal. J. E. Strandmark said that leonite is isomorphous with the artificial salt, $K_2Mn(SO_4)_2 \cdot 4H_2O$, but not with astrakanite, $Na_2Mg(SO_4)_2 \cdot 4H_2O$. Twinned crystals are found in the artificial preparations. The salt is soluble in water.

In his examination of the crystals of a salt produced at the eruption of Vesuvius in 1855, A. Scacchi found crystals of a mineral which was called *picromerite* in allusion to the magnesia present. The same crystals occur in the Stassfurt salt deposits along with kieserite and carnallite. Most of the impurities present as

chlorides can usually be removed by washing with alcohol. E. Reichardt called the mineral *schönite*—C. F. Zincken proposed kainite, but that name is reserved for another mineral. Analyses by M. Graf, E. Reichardt, R. Phillips, C. F. Rammelsberg, and others show that the composition is in agreement with **hexahydrated potassium magnesium disulphate**, $\text{K}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 6\text{H}_2\text{O}$, or $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. The crystals were obtained by A. Marcet from the bittern of sea-water, and by G. Busch from the mother liquid of the Lüneburg and Schönebeck springs. Schönite is obtained from soln. of potassium chloride and kieserite; from the leaching of kainite with water; and by evaporating the mixed soln. of the component salts to the point of crystallization.

According to T. C. McKay, when schönite is dissolved in water, it is decomposed more or less into its components, and from conductivity measurements, it follows that in conc. soln. some undecomposed double salt is still present, while in dil. soln., the salt is completely decomposed. The same conclusion follows from observations on the sp. gr. of aq. soln. which is smaller than that calculated for the components. The limits of existence and solubility relations have been described by J. K. van der Heide, J. H. van't Hoff, and H. S. van Klooster. The latter found that in aq. soln. of the two salts at 25° , the solid phase is $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ for conc. between 26.39 grms. of MgSO_4 and 7.02 grms. of K_2SO_4 per 100 grms. of sat. soln., where the solid phases are $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ and $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, and 12.68 grms. MgSO_4 and 10.70 grms. K_2SO_4 , where the solid phases are $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and K_2SO_4 —*vide* the solubility of magnesium sulphate in soln. of potassium sulphate. J. K. van der Heide showed that schönite decomposes into its components below -3° , and above 72° ; at 72° , in the presence of hexahydrated magnesium sulphate, schönite passes into leonite, and in the presence of potassium sulphate, the transition point is 92° . J. H. van't Hoff and P. Williams found that schönite passes into leonite at 47.5° , provided that an excess of potassium sulphate is present; at 41° if heptahydrated magnesium sulphate is present; and at 20° if the latter salt and also potassium chloride are present. Some equilibrium relations have been discussed in connection with Figs. 2-6, 2. 20, 3. According to W. D. Bancroft:

If one solid phase can be converted into one of the others by addition of water the inversion point is a maximum or a minimum temp. for one of those phases, and is neither a maximum nor a minimum for the third solid phase. For example, in the system: potassium sulphate, magnesium sulphate and water, at 47.2° , two of the phases are $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ and $\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$, the third is $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. This is a minimum temp. for the hexahydrate. The hydrated double salt exists both above and below the temp. of the inversion point. At 72° two of the solid phases are the hydrated double salts, $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, while the third is heptahydrated magnesium sulphate. At 92° two of the solid phases are the same two hydrated double salts and the third is potassium sulphate. The first temp. is a minimum for the double salt with four units of water, and the second a maximum for the one with six of water. If the temp. are not given it can only be told by experiment which point is which. If the compositions of the soln. are known, the direction of the temp. change can be foretold from the theorem of A. C. van Rijn van Alkemade that the temp. rises along the boundary curve in the direction of the line connecting the m.p. of the two solid phases. The higher temp. will necessarily be a maximum for the double salt with a larger amount of water of crystallization.

A. E. H. Tutton prepared the corresponding **hexahydrated rubidium magnesium disulphate**, $\text{Rb}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, and **hexahydrated caesium magnesium disulphate**, $\text{Cs}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, by the evaporation of soln. of the component salts. The crystals have been measured by H. J. Brooke, C. F. Rammelsberg, A. Murmann and L. Rotter, H. Töpsöe and C. Christiansen, J. C. Heusser, F. L. Perrot, etc. They belong to the monoclinic system. The ammonium, potassium, rubidium, and caesium salts form an isomorphous series. A. E. H. Tutton has made an exhaustive examination of the crystal constants of this series of salts and the corresponding series with zinc in place of magnesium, and with selenates in place of sulphates. He found the habit of the potassium salt is a stout primary prism with a large basal plane; that of the caesium salt is a clinodome-prism with a narrow

basal plate; and that of the ammonium salt gives all varieties. The axial ratios, the axial angle β , and the topic axes or distance ratios are indicated in Table I. The values for the ammonium salt are included.

TABLE I.—AXIAL RATIOS, TOPIC PARAMETERS, AND ANGLES OF THE SALTS:
 $M_2Mg(SO_4)_2 \cdot 6H_2O$.

	$a:b:c$	β	$\chi:\psi:\omega$	Sp. gr.	Mol. vol.
$K_2Mg(SO_4)_2 \cdot 6H_2O$	0.7413 : 1 : 0.4993	104° 48'	6.0711 : 8.1899 : 4.0892	2.034	196.58
$Rb_2Mg(SO_4)_2 \cdot 6H_2O$	0.7400 : 1 : 0.4975	105° 59'	6.1803 : 8.3518 : 4.1550	2.386	206.18
$(NH_4)_2Mg(SO_4)_2 \cdot 6H_2O$	0.7400 : 1 : 0.4918	107° 6'	6.2320 : 8.4217 : 4.1418	1.723	207.78
$Ca_2Mg(SO_4)_2 \cdot 6H_2O$	0.7279 : 1 : 0.4946	107° 6'	6.2608 : 8.6012 : 4.2541	2.676	218.96

A. E. H. Tutton deduces the following relations: (1) The value of the axial angle β in the rubidium salt is approximately midway between the values of the axial angles of the potassium and caesium salts. (2) The relative amounts of change brought about in the axial angle by replacing the alkali metal potassium by rubidium, and the rubidium in turn by caesium, are approximately directly proportional to the relative differences in the at. wt. of the metals interchanged. (3) The axial angle increases with the increase in the at. wt. of the alkali metal. (4) The values of all the angles of the rubidium salt lie between the corresponding values of the potassium and caesium salts, except in very rare cases, where more or less neutrality is produced owing to the changes in adjacent angles being of opposite sign. (5) The relative amounts of change in the angles other than the axial angle are rarely in direct simple proportion to the changes in at. wt. The maximum deviation from direct proportionality occurs in the prism zone at right angles to the zone containing the basal plane and orthopinacoid, and the relative amounts of change here bear the ratio of one to three. (6) The magnitude of the differences between most of the angular values of the three salts is surprisingly large, exceeding a whole degree in the cases of several important angles, and indicates a preponderating influence on the part of the alkali metals in determining the geometrical form of these double salts. (7) No indication of the full nature of the change brought about on replacing one metal by another in this isomorphous series is afforded by a comparison of the axial ratios, as simultaneous changes, which more or less neutralize each other, occur in the inclinations of the planes which determine them. The angles themselves alone furnish complete information concerning the change of external form. E. Blasius studied the corrosion figures of the ammonium salt.

J. W. Retgers found that the **specific gravity** of the mixed crystals of ammonium and potassium zinc sulphates varies linearly with the relative proportions of the two salts. The sp. gr. of the hexahydrated potassium salt has been found by L. Playfair and J. P. Joule to be 2.076 to 2.05319 at 4°; H. Schiff gave 1.995; H. Töpsöe and C. Christiansen, 2.204; H. Gerhart, 2.029; and H. G. F. Schröder, 2.039. The latter's values for the sp. gr. of the potassium salt which has been dehydrated without melting, range from 2.735 to 2.750. F. L. Perrot found 2.41 for the sp. gr. of the rubidium salt, and G. Wulff, 2.672 for the caesium salt. L. Playfair and J. P. Joule found for the hexahydrated ammonium salt 1.71686 at 4°; H. Schiff, 1.608; H. J. Buignet, 1.762; H. Töpsöe and C. Christiansen, and F. L. Perrot, 1.720; G. Wulff, 1.721; and H. G. F. Schröder, 1.725. A. E. H. Tutton's values, for the sp. gr., at 20°, referred to water at 4°, and **molecular volumes** of the potassium, rubidium, ammonium, and caesium series, are indicated in Table I. The rate of **diffusion** has been measured by C. Porlezza; and the heat of admixture of soln. of the component salts by R. Dubrisay.

The **refractive indices** have been determined by H. Töpsöe and C. Christiansen, F. L. Perrot, and A. E. H. Tutton. The last-named has given the results in Table II.

TABLE II.—REFRACTIVE INDICES OF THE SALTS $M_2Mg(SO_4)_3 \cdot 6H_2O$ at 20° .

The mean values for the refractive index and of the positive double refraction $\gamma - \alpha$ for Na-light, at 20° , are :

	K-salt.	Rb-salt.	NH_4 -salt.	Cs-salt.
Mean refractive index	1.4664	1.4713	1.4744	1.4877
Double refraction	0.0148	0.0107	0.0070	0.0059

A. E. H. Tutton found the refractive indices of the potassium salt decrease by 0.0015 to 0.0022 in raising the temp. from 20° to 70° ; with the rubidium salt the decrease is about 0.0015; with the caesium salt about 0.0016; and with the ammonium salt 0.0015 to 0.0019. The mean **molecular refractions** for the C-ray—Gladstone and Dale's formula—are 91.23 for the potassium salt, 96.74 for the rubidium salt, 98.03 for the ammonium salt, and 106.25 for the caesium salt.

When the potassium salt is heated to 100° , it loses about 18.48 per cent. of water; and T. Graham found all the water of crystallization is expelled at 132° . S. U. Pickering found the **heat of solution** of the dihydrated potassium salt to be 11.47 Cals. at 18° ; and of the hexahydrate, -9.96 Cals. J. Thomsen also gave for the heat of soln. of a mol of the salt $K_2SO_4 \cdot MgSO_4 \cdot nH_2O$, in 400 mols of water at 18° :

n	0	1	2	3	4	5	6 mols
Heat of soln. . . .	10.60	6.122	0.741	-2.038	-5.160	-7.954	-10.024 Cals.

J. F. Daniell and W. A. Miller gave data for the **transport numbers** of the ions.

E. Erlenmeyer represents the constitution of $MgSO_4 \cdot K_2SO_4$ by $KO \cdot SO_2 \cdot O \cdot Mg \cdot O \cdot SO_2 \cdot OK$, otherwise expressed by $Mg(KSO_4)_2$. W. Meyerhoffer and F. G. Cottrell prepared what they called an acid triple salt, $KHMg(SO_4)_2 \cdot 2H_2O$, or **potassium magnesium monohydro-disulphate**, $Mg(KSO_4)(HSO_4) \cdot 2H_2O$, by dissolving leonite, $K_2SO_4 \cdot MgSO_4 \cdot 4H_2O$, in 85 per cent. nitric acid and allowing the mixture to crystallize. The prismatic crystals are washed with absolute alcohol and ether, and dried at 60° . The crystals are doubly refracting. They are immediately decomposed by water, forming schönite, $K_2SO_4 \cdot MgSO_4 \cdot 6H_2O$.

K. Kubierschky assumed the existence of a triple salt *potassium sodium magnesium sulphate*, and possibly related to the *sodium-potassium-simonyites* in the salt deposits of Wilhelmshall; but J. H. van't Hoff and H. Barschall showed that isomorphous mixtures of astrakanite and leonite are involved, but no compound is formed.

E. Bechi³ found ammonium sulphate with part of the alkali replaced by magnesium about the boric acid fumaroles of Tuscany; and he named the mineral *boussingaultite*; it has been described by O. Popp, who re-christened it *cerbolite*. It seldom occurs in a high degree of purity, but when recrystallized from water, analyses agree with its being **hexahydrated ammonium magnesium disulphate**, $(NH_4)_2SO_4 \cdot MgSO_4 \cdot 6H_2O$, or $(NH_4)_2Mg(SO_4)_2 \cdot 6H_2O$. According to J. J. Berzelius, the salt is readily precipitated as a crystalline powder on mixing conc. soln. of the

component salts; or by passing ammonia into a soln. of magnesium sulphate in dil. sulphuric acid; and its preparation and composition were studied by C. J. B. Karsten, T. Graham, etc. The crystallographic data, sp. gr., and optical constants have been discussed in connection with the corresponding potassium salt with which it is isomorphous. C. Borel found the dielectric constant of magnesium ammonium sulphate for $\lambda = \infty$, to be 8.54 for the symmetry axis. According to H. Rheineck, at 120°, the crystals lose 25.8–26.1 per cent. of water, and at a higher temp. they melt and decompose. The crystals, dried at 100°, were found by T. Graham to lose all their water and become anhydrous at 132°. H. G. F. Schröder gave 2.105 for the sp. gr. of the dehydrated salt. The crystals are less soluble in water than either of their component salts; G. J. Mulder stated that at 13°, 100 parts of water dissolved 15.9 parts of $(\text{NH}_4)_2\text{Mg}(\text{SO}_4)_2$; and, according to E. Tobler, 100 grms. of water dissolve at:

	0°	10°	20°	30°	45°	50°	60°	75°
$(\text{NH}_4)_2\text{Mg}(\text{SO}_4)_2$. . .	9.0	14.2	17.9	19.1	25.6	30.0	36.1	45.8 grms.

J. Lothian obtained rather higher results; he found that 100 grms. of water dissolved 18.22 grms. of the double salt at 1.1°; 20.72 grms. at 5°; 22.48 grms. at 10°; 24.08 grms. at 15°; 24.81 grms. at 15.5°; 28.26 grms. at 20.5°; and 33.33 grms. at 27.2°. According to C. F. Lindsay, the electrical conductivity of a conc. soln. is smaller than that of either of the components at the same conc.; and H. C. Jones and B. P. Caldwell estimate that the salt is completely dissociated at a conc. of a 0.005N-soln. F. Rüdorff, D. M. Torrance and N. Knight, H. L. Maxwell, and C. Porlezza studied the dissociation of the salt by diffusion experiments. A. Weston studied the quaternary system: K_2SO_4 — Mg_2SO_4 — $(\text{NH}_4)_2\text{SO}_4$ — H_2O . G. Spacu and R. Ripan prepared **magnesium tetraquodiamminosulphate**, $[\text{Mg}(\text{NH}_3)_2(\text{H}_2\text{O})_4]\text{SO}_4$, as a crystalline powder; **magnesium triaquotriamminosulphate**, $[\text{Mg}(\text{NH}_3)_3(\text{H}_2\text{O})_3]\text{SO}_4$, in colourless crystals; **magnesium diaquodiamminosulphate**, $[\text{Mg}(\text{NH}_3)_2(\text{H}_2\text{O})_2]\text{SO}_4$, as a white powder. They also made complexes with piperidine, and benzylamine. G. Spacu made a complex with triethylenediamine.

The mineral *kainite* occurs as yellowish-greyish or greenish masses in the salt deposits of Stassfurt, Westeregeln, Kalucz in Galicia, etc.; its name is derived from *καίνος*, recent. Analyses correspond with **trihydrated potassium magnesium chlorosulphate**, $\text{KCl} \cdot \text{MgSO}_4 \cdot 3\text{H}_2\text{O}$, or possibly with $\text{K}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$. The former was recommended by W. Meyerhoffer,⁴ G. Tschermak, A. de Schulten, and E. Erlenmeyer, and the latter by A. Frank. The formula may also be written $\text{Mg}(\text{KSO}_4)\text{Cl} \cdot 3\text{H}_2\text{O}$.

$\text{Mg} < \begin{smallmatrix} \text{Cl} \\ \text{Cl} \end{smallmatrix}$	$\text{Mg} < \begin{smallmatrix} \text{Cl} \\ \text{KSO}_4 \end{smallmatrix}$	$\text{Mg} < \begin{smallmatrix} \text{KSO}_4 \\ \text{KSO}_4 \end{smallmatrix}$	$\text{Mg} < \begin{smallmatrix} \text{HSO}_4 \\ \text{KSO}_4 \end{smallmatrix}$
Magnesium chloride.	Kainite.	Leonite or Schönite	Monohydrodisulphate.

In 1843, C. J. B. Karsten noticed that no precipitation occurs on mixing conc. soln. of potassium chloride and magnesium sulphate, but crystals appear when the soln. has stood for some hours. A. de Schulten prepared kainite by evaporating on a water-bath a mixed soln. of 40 grms. of potassium sulphate and 80–90 grms. of magnesium sulphate with a great excess (500 grms.) of hexahydrated magnesium chloride. The crystals are removed from the mother liquid by press. or suction, and washed with absolute alcohol. If a smaller proportion of magnesium sulphate is employed, the product is contaminated with carnallite. The conditions of formation of kainite have been studied by J. H. van't Hoff and W. Meyerhoffer. The former showed that what he called a *tetragenic salt*—i.e. one with four different elements or radicles, exclusive of the water of crystallization—must have at least two and it may have three temp. of formation; the temp. of formation of kainite are 76° and 85°, and the *polytherms*, or the equilibrium relationships of kainite at different temp., show that besides the above primary temp. of formation, other lower secondary temp. of formation exist.

The crystals of kainite were shown by P. Groth to be monoclinic prisms with axial ratios $a : b : c = 1.2186 : 1 : 0.5863$, and $\beta = 94^\circ 54' 30''$. For this sp. gr. of kainite, C. F. Zincken gave 2.131; E. Reichardt, 2.133 to 2.154; V. von Zepharovich, 2.151; and A. de Schulten, 2.120, at 15° , for the artificial product. The hardness is 2.5 to 3.0. The double refraction is negative. According to C. F. Rammelsberg, kainite effloresces on standing over conc. sulphuric acid. C. F. Zincken, and A. Frank observed that kainite loses water and hydrogen chloride when heated. In moist air, water is absorbed, magnesium chloride is washed out, and schönite remains; water and alcohol decompose it in a similar way. According to G. Krause, 100 parts of water at 18° dissolve 79.56 parts of kainite; and J. G. Lehmann noted that a mixture of equal parts of alcohol and ether, which dissolves magnesium chloride, does not dissolve kainite.

The triple salts, *polyhalite*, $2\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and *krugite*, $4\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, occur in the Stassfurt salt deposits. Polyhalite was named by F. Stromeyer⁵ from πολύς , many, $\alpha\lambda\varsigma$, salt, in reference to the number of the component salts which make up the mineral. It occurs associated with gypsum, anhydrite, and rock salt in the salt deposits at Ischl, Ebensee, Aussee, Hallstadt, and Hallein in Austria; at Berchtesgaden in Bavaria; at Vic in Lorraine; and the various Stassfurt deposits. Analyses have been reported by F. Stromeyer, C. F. Rammelsberg, W. Dexter, C. A. Joy, K. von Hauer, P. Berthier, J. B. Schober, G. Jenzsch, F. Bischof, E. Reichardt, etc. In the main, these agree with the composition: $2\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, **dihydrated magnesium potassium dicalcium sulphate**. M. Rosza has shown that the occurrence of polyhalite in different parts of the salt deposits is in good agreement with the work of J. H. van't Hoff. A. Goebel found nodules of a white mineral resembling polyhalite, and associated with the carnallite of the salt mines at Maman (Persia), and hence named *mamanite*. The ratio of the calcium, magnesium, and potassium sulphates is as 3 : 2 : 1. According to J. H. van't Hoff and G. L. Voerman, *mamanite* is an impure polyhalite. According to E. E. Basch, polyhalite is formed at 25° in a soln. containing syngenite, gypsum, and epsomite. The region of its existence is narrow. Soln. containing per litre :—

K_2SO_4	MgSO_4	Solid phases.
3.5	56.7	Polyhalite, gypsum, syngenite
3.6	55.7	Polyhalite, gypsum, epsomite
5.1	58.1	Polyhalite, syngenite, epsomite

The equilibrium conditions are illustrated diagrammatically in Fig. 25, although H. S. van Klooster has shown that there is probably something wrong in E. E. Basch's

FIG. 25.—Conditions for the Formation of Polyhalite (25°).

results. Polyhalite is probably rhombic, its sp. gr. is 2.769, and its hardness 2.5 to 3. According to H. Rose, it melts when heated, and on cooling solidifies to an amorphous mass. Polyhalite is decomposed with difficulty by cold water, and leaves a residue of calcium sulphate, while potassium and magnesium sulphates pass into soln. It is more rapidly decomposed by hot water. The dehydrated salt hardens when mixed with water, and forms a voluminous mass, which is readily separated into its constituents by water. J. H. van't Hoff, F. Farup, and J. d'Ans have further studied the formation of polyhalite in the presence of "sea-salts."

H. Precht analyzed a crystalline mineral resembling polyhalite, which he found at the salt-works of New Stassfurt. Its analysis corresponds with $4\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, **dihydrated magnesium potassium tetracalcium sulphate**, and it is supposed to be a mixture of polyhalite and anhydrite, even though it appears homogeneous under the microscope. It was named *krugite* after the mining director, D. Krug von Nidda. The sp. gr. of *krugite* is 2·801, and its hardness 3·5. With cold water, magnesium sulphate is dissolved, and a double salt, $\text{K}_2\text{SO}_4 \cdot \text{CaSO}_4 \cdot \text{H}_2\text{O}$, remains insoluble, and with hot water, it acts like polyhalite, dissolving magnesium and potassium sulphates, and leaving the gypsum undissolved.

According to J. H. van't Hoff and A. P. Saunders,⁶ if an aq. soln., containing the sulphates and chlorides of potassium, sodium, and magnesium, and sat. with sodium chloride, be evaporated at 25°, sodium and potassium chlorides; carnallite, $\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$; bischoffite, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$; hexa- and hepta-hydrates of magnesium sulphate; schönite, $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$; glaserite, $\text{K}_3\text{Na}(\text{SO}_4)_2$; penta- and tetra-hydrates of magnesium sulphate; thenardite, Na_2SO_4 ; and astrakanite, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, crystallize from the soln., but not langbeinite, $\text{K}_2\text{Mg}_2(\text{SO}_4)_3$; Glauber's salts, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$; nor löweite, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$. The formation of potassium sulphate; kieserite, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$; kainite, $\text{KCl} \cdot \text{MgSO}_4 \cdot 3\text{H}_2\text{O}$; and leonite, $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, occurs only under special conditions; for example, J. H. van't Hoff and P. Williams state that supersaturation phenomena prevent the appearance of leonite. J. H. van't Hoff and co-workers have shown that at 25°, soln. with 1000 mols of water sat. with one, two, three, or four other salts have the compositions, and vap. press. in mm. of mercury, shown in Table III.

TABLE III.—LIMITS OF EXISTENCE OF SALT MINERALS.

1000 mols $\text{H}_2\text{O} \rightarrow$	Na_2Cl_2	MgCl_2	K_2Cl_2	Na_2SO_4	MgSO_4	mm.

J. H. van't Hoff represented these results graphically, and applied them to the phenomena which occur during the evaporation of sea-water, and which were studied by J. Usiglio. Kainite and kieserite did not appear owing to supersaturation; and when the effects of this phenomenon were eliminated, the compositions of the soln. sat. with different salts are shown in Table IV.

TABLE IV.—LIMITS OF EXISTENCE OF SALT MINERALS.

1000 mols H ₂ O sat. with	Na ₂ Cl ₂	MgCl ₂	K ₂ Cl ₂	MgSO ₄
Kainite; NaCl; epsomite; leonite . . .	9	45	7.9	19.5

Leonite, K ₂ Mg(SO ₄) ₂ .4H ₂ O . .	61.5°	89°	Langbeinite, K ₂ Mg ₂ (SO ₄) ₃
Kainite, KCl.MgSO ₄ .3H ₂ O . . .	83°	85°	Hard salt, MgSO ₄ .H ₂ O and KCl

i.e. the origin of the salt minerals between 25° and 83°, it was found convenient to divide the temp. interval into three periods. The first ranges from 25° to 37°, and here the limits for the phases schönite, epsomite, and MgSO₄.6H₂O gradually become less, or disappear, as illustrated diagrammatically in the schemes I to V, Fig. 26. The appearance or disappearance of a new phase is represented by a blackened circle. In the second period, between 37° and 55°, langbeinite, löweite, and vanthoffite appear as new phase, as illustrated in VI to VIII, Fig. 26. In the third period, ranging from 55° to 83°, astrakanite, löweite, and kainite disappear, as illustrated IX to XII, Fig. 26. Below 25°, many of the phases disappear, and at 18°, Glauber's salt appears, and kieserite disappears; at 13.5°, thenardite disappears; and at 13°, the hexahydrate, MgSO₄.6H₂O, disappears.

J. H. van't Hoff and co-workers⁷ have also studied systems containing potassium, sodium, and magnesium chlorides and sulphates with calcium sulphate in addition. The range of existence of the different salt minerals is indicated. The limiting soln. for syngenite and polyhalite at 83° are indicated in Table VI.

TABLE VI.—LIMITS OF EXISTENCE OF THE SALT MINERALS AT 83°.

1000 mols of H ₂ O→	Na ₂ Cl ₂	K ₂ Cl ₂	MgCl ₂	MgSO ₄	Na ₂ SO ₄	CaSO ₄	CaCl ₂

§ 14. Magnesium Carbonate

Anhydrous normal magnesium carbonate, MgCO_3 , occurs in nature as the mineral *magnesite*. This was discovered at Hrubschütz (Moravia), and named *Kohlensaurer Talkerde* by W. A. Lampadius (1800);¹ and *reine Talkerde*, or *Talcum carbonatum*, by C. F. Ludwig (1803). J. C. Delamétherie (1795) applied the term *magnesite* to a series of magnesium salts—carbonate, sulphate, nitrate, and chloride; and A. Brongniart applied the same term to a group of minerals including magnesium carbonate, and a series of siliceous varieties. The carbonate came first in both series of magnesites, and the term *magnesite* was formally reserved for the carbonate by D. L. G. Karsten in 1808. This was gradually accepted by the German mineralogists, though, in France, F. S. Beudant's term *giobertite* for the carbonate, and his *magnesite* for the silicate prevailed for a long time. J. C. Delamétherie used *baudissierite* for a siliceous earthy variety from Baudissero near Turin which was analyzed by G. A. Giobert; this variety of *magnesite* resembles chalk, and sticks to the tongue.

There are two main types of *magnesite*—the one type is amorphous or a gel colloid, and is represented by the compact, granular, and cleavable forms; and the other type occurs in distinct rhombohedral or trigonal crystals. A. Breithaupt called the former *magnesite* and the latter *magnesite spar*; but *magnesite* is now applied to both forms. *Magnesite* usually contains some iron, possibly as ferrous carbonate, siderite, and the colour may be white, yellow, brown, or rarely black.

The light-coloured ferruginous magnesites often become brown on exposure; hence the name brown spar. A variety containing 5–10 per cent. ferrous oxide was called by W. Haidinger, after M. Breuner, *breunnerite*; and a variety analyzed by L. P. Walmstedt, containing a little more manganese oxide than usual was called *walmstedtite* by K. C. Leonhard. A. Breithaupt named one variety *mesitite* or *mesitine*—*μεσιτίνης*, a go-between—being intermediate in composition between siderite and *magnesite*; and another variety, with a little more iron and nearer the mean composition of *magnesite* and siderite, was called *pistomierite*—*πιστοίτης*, truly.

Magnesite is formed in nature as a product of the action of carbonated waters on the more easily decomposed magnesium rocks—e.g. peridotites and serpentines.² The *magnesia* is dissolved as carbonate and may be deposited elsewhere along with more or less opaline silica formed at the same time. Ferrous carbonate may also be formed and produce a mixed carbonate. Instead of depositing their contained magnesium carbonate, these waters may act on limestone or dolomite, replacing the calcium by magnesium. *Magnesite* may also be formed as a sedimentary deposit, for H. S. Gale observed that near Bisnell, California, *magnesian salt soln.* mix with sodium carbonate, and deposit basic magnesium carbonate.

No deposits of *magnesite* of any industrial importance are known in the British Isles. Large deposits of crystalline *magnesite* occur in Austria and Hungary—principally

at Veitsch, and other places in Styria, and about Jolsva and Nyusta in N.-W. Hungary; they follow a N.-E. and N.-W. line crossing Vienna and Budapest. Deposits are also worked at Kraljevo, Serbia. There are very important deposits of chalk-like magnesite in the northern part of the Island of Euboea, Greece; and there are deposits on the Chalcidice peninsula, Macedonia. In Italy, compact magnesite has been quarried at Castiglione, Monterufoti on the Island of Elba, and also in Turin. In Norway, spathic magnesite is worked at Snarum, Modum. In Russia, at Mt. Boltscheja, there are quarries of magnesite resembling that from Austria. There is a small output of compact magnesite from Spain—Esperanza and San Jose, Santander, and La Papa, Almeria. Large deposits of compact magnesite occur in the Barberton district, Eastern Transvaal, S. Africa. In India, compact magnesite is mined in the Chalk Hills of the Salem district, Madras; and there are deposits at Dod Kanya and Dod Katur, Mysore. Compact magnesite occurs in many parts of Australia—Fifield, N.S.W.; Heathcote, Victoria; Marlborough and Kunwarara, Queensland; Tumbay Bay, South Australia; and at Bulong, Western Australia. In Canada there are large deposits of lenticular masses of magnesite in the Grenville district, Quebec; and in British Columbia there are deposits of compact magnesite and of hydromagnesite. Most of the magnesite mined in the United States is of the Grecian type and comes from California, where it occurs on the western side of the Sierra Nevada in the Tulare, Sonoma, Santa Clara, and Kern counties; and crystalline magnesite occurs in Stevens County, Washington. Compact magnesite occurs on the Island of Margarita, Venezuela. Compact magnesite also occurs in Manchuria. Bibliographies have been published by the Imperial Mineral Resources Bureau, etc.³ There are many of the deposits in which the magnesite may occur in veins too thin to work profitably, and many would be workable if more favourably situated for transport.

Numerous analyses of selected specimens have been reported.⁴ The material is blasted from the sides of the quarry, and broken to one-man pieces, and the particles of gangue—dolomite, quartz, serpentine, calcite, and other impurities—are removed by cobbing, etc. The extremes in some commercial samples of raw magnesite are indicated in Table VII. Small proportions of manganese oxide,

TABLE VII.—COMMERCIAL ANALYSIS OF MAGNESITE.

	Austro-Hungarian.	Grecian.	Indian.	Californian
SiO ₂ . .	0.45-5.83	0.20-1.63	0.22-1.17	0.73-7.67

phosphoric acid, calcium carbonate, alkalies, and combined water may be present. F. Accum discussed the separation of argillaceous matter from magnesite.

Magnesite is marketed in three forms: (i) *Crude or raw magnesite* as produced at the mine. (ii) *Caustic magnesite* has been calcined at a red heat. It consists mainly of magnesia, and it still retains 2 to 4 per cent. of carbon dioxide. It slakes in contact with water, and combines with magnesium chloride to form Sorel's cement. The calcination of the purer forms of magnesite has at times been effected in retorts so as to obtain the carbon dioxide for making effervescent beverages. (iii) *Dead-burned magnesite* is calcined at as high a temp. as is practicable. It contains less than one per cent. of carbon dioxide. It is hard, dense, and non-plastic and is chemically inert, for it does not slake in air or in water; but it tends to disintegrate when exposed to steam.⁵ The shrinkage in making dead-burned magnesite approaches 50 per cent., and the product, if the calcination has been adequately performed, has lost nearly all its shrinking power. It is mainly used for the manufacture of magnesia (*i.e.* magnesite) bricks.

The preparation of normal magnesium carbonate.—T. Bergman,⁶ in his essay *De acido aëreo* (Upsala, 1774), described the formation of magnesium carbonate. There is a tendency for magnesium carbonate to separate from its aq. soln. in a hydrated form, or if precipitated it undergoes more or less hydrolysis and appears

as basic carbonate. W. Bramley and W. P. Cochrane heated a soln. of an alkali or ammonium hydro-carbonate or sesqui-carbonate in a closed vessel with magnesia. Hydrated magnesium carbonate is formed, and the hydro- or sesqui-carbonate is converted into normal carbonate. Magnesium carbonate and magnesia alba were found by J. J. Berzelius to contain alkali carbonate and occluded chlorides or sulphates. The alkali carbonate cannot be removed by repeated extraction with boiling water, but W. A. Davis purified the carbonate by dissolving it in water through which carbon dioxide was passing; and decomposing the filtered soln. by boiling. If necessary the treatment is repeated on the washed product. H. de Sénarmont obtained a granular mass of crystals of anhydrous magnesium carbonate by the action of sodium carbonate on magnesium sulphate in a sealed tube between 160° and 175° ; he also obtained a similar product from a soln. of magnesium carbonate in carbonic acid at about 155° . R. Marc and A. Simek made anhydrous rhombohedral crystals of magnesite by heating 10 grms. of the precipitated carbonate with 300 c.c. of water and a few grms. of solid carbon dioxide in a sealed tube, in an autoclave at 185° and a press. of 20–30 atm. H. Rose found that if the soln. be evaporated to dryness crystals of magnesite resembling aragonite are produced as well as the basic carbonate—magnesia alba. If this be correct, magnesium carbonate is dimorphous like calcium carbonate. L. Bourgeois found that precipitated magnesium carbonate furnishes crystals of magnesite when heated with urea in a sealed tube at 140° ; if ammonium nitrate be used in place of urea, the crystallization does not take place. O. Brill obtained a flocculent form of anhydrous magnesium carbonate by heating the basic carbonate; or precipitation by alkali carbonate from a soln. of a magnesium salt, between 150° and 220° , in an atm. of dry carbon dioxide. C. Heyer proposed to remove the alkali, which adheres very tenaciously to the precipitate, by heating the mass, and then washing out the alkali. A. Röhrig, and J. Treumann heated under press. a soln. of a magnesium salt with calcium carbonate. R. Engel obtained crystals of magnesite by heating ammonium magnesium carbonate, $(\text{NH}_4)_2\text{Mg}(\text{CO}_3)_2 \cdot 4\text{H}_2\text{O}$, in a stream of dry air between 130° and 140° . The corresponding potassium salt furnishes a similar result at 200° , and the alkali carbonate can be washed out with cold water.

C. Neuberg and B. Rewald⁷ prepared **colloidal magnesium carbonate** by passing a stream of carbon dioxide into a methyl alcohol soln. of magnesium oxide; the opaque liquid clears in about 24 hrs. Water flocculates the colloidal soln.

The physical properties of anhydrous magnesium carbonate.—The natural crystals belong to the trigonal system⁸ and have the axial ratio $a:c=1:0.8095$ with $\alpha=103^{\circ} 21\frac{1}{2}'$. Magnesium carbonate is the first member of a series of isomorphous carbonates, including calcium, manganous, ferrous, zinc, and cadmium carbonates. If G. Rose's statement—*vide supra*—be correct, magnesium carbonate, like calcium carbonate, is dimorphous. A. W. Hull⁹ studied the **X-radiogram**. The **specific gravity** has been determined by many observers, and the reported values for crystalline magnesite range from A. Breithaupt's, and R. F. Marchand and T. Scheerer's 3.017, to A. Jentsch's 3.076. The best representative value approaches 3.037; for amorphous magnesite W. Beck, and R. F. Marchand and T. Scheerer give 2.934; K. Grünberg gives 2.822 for the sp. gr. of magnesium carbonate, and 3.27 for that of ferrous carbonate; and the sp. gr. of isomorphous mixtures of the two changes linearly between these limits. W. Beck's value for the **molecular volume** is 27.38. The **hardness** of crystalline magnesite ranges between $3\frac{1}{2}$ and $4\frac{1}{2}$; amorphous magnesite, with more or less silica, may be still harder than this. This subject has been discussed by A. Reis and L. Zimmermann.

H. Fizeau found the **coefficient of thermal expansion** in the direction of the principal axis to be $\alpha=0.00002130$, and in a direction normal to this, $\alpha'=0.00000599$. R. Ulrich and F. Wollny found the **specific heat** of magnesite to be 0.2438 between 17° and 99° ; and, for artificial magnesium carbonate, 0.2456. A. S. Herschel gave 0.24 for the sp. ht. of magnesite. The **heat of formation**, according to M. Berthelot for the precipitated carbonate (Mg , 3O, C)=266.6 Cals., or $(\text{CO}_{2\text{aq.}}, \text{MgO}_{\text{aq.}})=17.9$

Cals.; and $\text{K}_2\text{CO}_{3\text{aq.}} + \text{MgSO}_{4\text{aq.}} = \text{MgCO}_3 + \text{K}_2\text{SO}_{4\text{aq.}} + 2.1$ Cals. R. de Forcrand gives $(\text{MgO}, \text{CO}_2) = 28.9$ Cals. R. Marc and A. Simek give -23.2 Cals. for the heat of dissociation of magnesium carbonate. J. Johnston gives for the **free energy** of the dissociation carbonate to oxide 11,700 cals. at 25° . E. Mallard gave for the **index of refraction** of natural crystals for Na-light $\omega = 1.717$ for the ordinary ray, and $\epsilon = 1.515$ for the extraordinary ray; the **double refraction** is strongly negative. W. Orloff's value for the **refraction equivalent** for the ordinary ray is 19.63, and for the extraordinary ray, 14.10, when calculated from Gladstone and Dale's formula. According to P. Bary, magnesite exhibits no fluorescence with **Becquerel's rays** or **Röntgen's rays**. L. Knobloch found the **contact electricity** of powdered magnesite with a plate of platinum, paraffin, or sulphur was negative, and positive with a plate of glass.

The action of heat on magnesium carbonate.—The conclusions drawn by different observers are not always in agreement. H. Rose¹⁰ stated that magnesium carbonate begins to lose carbon dioxide between 200° and 300° , and that when heated to a dull red heat all the carbon dioxide is lost; *au contraire*, R. F. Marchand and T. Scheerer stated that after a prolonged calcination at a bright red heat, the product still retains carbon dioxide. W. C. Anderson found the lowest temp. at which magnesite begins to lose carbon dioxide is 405° ; with the so-called heavy carbonate, the temp. is 368° , with light carbonate, 352° , and with crystal carbonate, 271.5° ; in the case of light and crystal carbonates, the expulsion of carbon dioxide was stated to be complete at about 750° , while the heavy carbonate retains a little of its carbon dioxide at temp. over 810° . H. le Chatelier found under atm. press. carbon dioxide is given off from magnesite at 680° ; and J. A. Hedvall gave 546° for the **dissociation temperature**. K. Friedrich and L. G. Smith found the decomposition of magnesite begins about 570° , and a maximum thermal change in the heating curve occurs at about 600° . A. Vesterberg found that magnesite decomposes more readily than dolomite; that magnesite first gives off carbon dioxide at 448° , and loses virtually all that gas when heated for an hour at 500° , whereas dolomite loses but little if any carbon dioxide at that temp. E. Wulfing also found that the temp. at which magnesite decomposes rapidly is but little over 500° , while with dolomite the temp. is much higher than this. J. Johnston gives for the **dissociation pressure** at 25° , 2.6×10^{-9} atm., and for the dissociation temp. 230° at 760 mm.; for the latter, R. Marc and A. Simek give 402° .

O. Brill studied the dissociation of artificial normal magnesium carbonate and, starting with 68.70 grms., he measured the loss in weight after heating 10 mins. at different temp. ranging from 135° to 630° . The following is a selection from a few of his measurements of the weight after heating to different temp.:

	135°	237°	265°	300°	340°	360°	435°	465°	500°	630°
Grms. . .	68.70	67.90	64.65	64.10	63.45	62.90	59.75	41.10	38.15	32.95

The whole of the results are plotted in Fig. 27. There appears to be a series of breaks in the curve. He considers that this proves that the decomposition of magnesium carbonate takes place in a series of stages corresponding with the formation of a series of basic carbonates each of which has a definite dissociation temp. The carbonates with their dissociation temp. are as follows:—

$10\text{MgO} \cdot 9\text{CO}_2$	$9\text{MgO} \cdot 8\text{CO}_2$	$8\text{MgO} \cdot 7\text{CO}_2$	$7\text{MgO} \cdot 6\text{CO}_2$	$6\text{MgO} \cdot 5\text{CO}_2$	$5\text{MgO} \cdot 4\text{CO}_2$	$7\text{MgO} \cdot \text{CO}_2$
265°	295°	325°	340°	380°	405°	510°

As W. A. Davis has pointed out, the fact that O. Brill worked with a hygroscopic magnesium carbonate having the composition $\text{MgCO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, deprives his results of real significance as examples of the dissociation of magnesium carbonate. The presence of water caused the material to break down at 230° , a much lower temp. than that required for the dissociation of magnesite, but approaching the temp. required for the decomposition of the trihydrate. R. Marc and A. Simek also emphasize the fact that precipitated magnesium carbonate retains water very

tenaciously. K. Friedrich and L. G. Smith observed no discontinuities. Accordingly the breaks are probably due to some cause other than the formation of basic carbonates. Measurements of the dissociation of dried magnesium carbonate are unsatisfactory because of the slowness of the change; and the presence of water vapour accelerates the change without disturbing the results because magnesium hydroxide dissociates at 180° at atm. press. The presence of fused potassium nitrate also stimulates the reaction. According to K. Grünberg, when a mixture of artificial magnesite, dolomite, and calcite is heated in a stream of hot air, in a silica vessel, the magnesite is completely decomposed at 410° ; the dolomite loses carbon dioxide corresponding with the magnesia content at 500° , and with the lime content at 530° ; and finally the calcite is decomposed at 570° . E. Reichardt and T. P. Blumtrill found that 100 grms. of magnesium carbonate absorb 720 c.c. of gas from the air, and the vol. composition of the gas is 64 per cent. nitrogen, 7 per cent. oxygen, and 29 per cent. carbon dioxide.

§ 15. Hydrated Magnesium Carbonates

Several hydrates of normal magnesium carbonate, $\text{MgCO}_3 \cdot n\text{H}_2\text{O}$, have been reported, where n may be 1, 2, 3, $3\frac{1}{2}$, 4, and 5. It is, however, by no means clear if all of them are chemical individuals, and it has been argued that the trihydrate is a hydrated basic hydrocarbonate. H. Beckurts¹ succeeded in making only the trihydrate. It is fairly obvious that the equilibrium relations of the hydrated normal carbonates require examination in the light of the phase rule.

E. A. Nørgaard is the authority for the report of the first two of these hydrates; he claimed to have made monohydrated magnesium carbonate, $\text{MgCO}_3 \cdot \text{H}_2\text{O}$, as a granular precipitate, by heating a dil. or conc. soln. of magnesium carbonate in carbonic acid, or in a soln. of magnesium sulphate, but not sufficiently high for the evolution of carbon dioxide. He said the precipitate is not changed by washing. The analysis 38.03 per cent. MgO agrees as well with a mixture of $\text{Mg}(\text{OH})_2 + \text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ as with $\text{MgCO}_3 \cdot \text{H}_2\text{O}$. E. A. Nørgaard made dihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 2\text{H}_2\text{O}$, by precipitation, by adding sodium carbonate to an excess of a soln. of magnesium sulphate—between 18° and 20° the precipitate is amorphous. The temp. falls from 20° to 3.5° during its formation, and rises 3.5° to 5° during its passage to the crystalline state. The analysis 34.06 per cent. MgO agrees with a mixture of $\text{Mg}(\text{OH})_2 + \text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ as well as with $\text{MgCO}_3 \cdot 2\text{H}_2\text{O}$. From the work of W. A. Davis, it is probable that the so-called monohydrated magnesium

carbonate is magnesium hydroxycarbonate, $\text{Mg}(\text{HCO}_3)(\text{OH})$, and the so-called dihydrated magnesium carbonate is a mixture of anhydrous magnesium hydroxycarbonate and of its dihydrate, $\text{Mg}(\text{HCO}_3)\text{OH} \cdot 2\text{H}_2\text{O}$. According to T. C. W. Bröksmit, the amorphous precipitate obtained by adding sodium, potassium, or ammonium carbonate, or hydrocarbonate to a soln. of magnesium sulphate, and generally supposed to be a basic carbonate, becomes crystalline after some time, and may be trihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$.

The rare mineral *nesquehonite*, trihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, was discovered in the anthracite mine of Nesquehoning, Lansford, Pa., and described by F. A. Genth and S. L. Penfield (1890). The mineral was first observed as being formed as stalactites in one of the galleries. It was also found by G. Friedel at Isère (France), and by H. Leitmeier as a deposit from the mineral springs at Rohitsch-Sauerbrunn (Unterstermark) at about 6°. According to J. J. Berzelius, the trihydrate is formed when a soln. of magnesium carbonate in aq. carbonic acid is allowed to evaporate spontaneously in air; or, according to J. Fritzsche, when the soln. sat. with carbon dioxide under press. is kept above 20°—the Salzbergwerk Neu-Stassfurt has a number of patents involving modifications of these processes. H. Leitmeier found the soln. furnishes the basic carbonate, $\text{Mg}_4\text{C}_3\text{O}_{10} \cdot 6\text{H}_2\text{O}$, from the b.p. down to 60°–65°; from 60°–55°, the basic carbonate is mixed with the trihydrate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$; at still lower temp. the trihydrate forms alone; and below 10°, the pentahydrate, $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$, appears. C. Kippenberger found that crystals of his $\text{MgCO}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$ form the trihydrate when allowed to stand in dry air, or over sulphuric acid. J. Fritzsche observed that the pentahydrate loses two-fifths of its water and forms the trihydrate when exposed in a glass tube to sunlight; and when treated in other ways—*vide infra*. According to A. F. de Fourcroy, and V. Rose, a mixture of aq. soln. of magnesium sulphate and sodium or potassium hydrocarbonate is initially clear, but it deposits crystals of the trihydrate when allowed to stand for some time; according to J. B. J. D. Boussingault, sodium sesquicarbonate can be used in place of the hydrocarbonate. Again, J. Fritzsche, E. Soubeiran, and P. A. Favre found that the precipitate which normal sodium carbonate gives with a soln. of magnesium sulphate is converted into crystals of the trihydrate if allowed to stand for a few days at a temp. between 0° and 10°—E. A. Nörgaard added that it is best to use an excess of magnesium sulphate, and if the temp. is below 22°, the pentahydrate is formed. According to a patent of the Salzbergwerk Neu-Stassfurt, a soln. of potassium magnesium carbonate reacts with magnesia: $2(\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}) + \text{MgO} = \text{K}_2\text{CO}_3 + 3(\text{MgCO}_3 \cdot 3\text{H}_2\text{O})$ at temp. between 20° and 50°.

According to W. A. Davis, the salt which is supposed to be the trihydrated normal carbonate is really a dihydrated magnesium hydroxycarbonate,

This opinion is based on the fact that the salt loses only two-thirds of its water when heated at 100° in a current of air, or boiled with a liquid like xylene (b.p. 137°); the remaining third of the water is expelled only at a much higher temp., and always together with some carbon dioxide.

W. A. Davis prepared dihydrated magnesium hydroxycarbonate, the so-called trihydrated magnesium carbonate, by mixing cold soln. of eq. quantities of sodium carbonate and magnesium sulphate, each dissolved in 15 parts of water. The precipitate first formed was left in contact with the mother liquor when it became entirely crystalline. The mother liquid, after standing for three months, had deposited a further crop of needle-like crystals. In both cases, the crystals had the composition $\text{Mg}(\text{HCO}_3)\text{OH} \cdot 2\text{H}_2\text{O}$. The conversion of the dihydrate into the anhydrous salt, $\text{Mg}(\text{HCO}_3)\text{OH}$, is effected as previously indicated.

The mode of formation of this salt shows that a basic carbonate cannot be produced by the decomposition of the hydroxyhydrocarbonate by water at the ordinary temp.; the crystals separated from the mother liquor remained in contact with water containing a slight excess of alkaline carbonate during three months,

and yet contained magnesia and carbon dioxide in the ratio corresponding with a normal carbonate. Water, free from alkali, is practically without action on magnesium hydroxyhydrocarbonate at ordinary temp. W. A. Davis supposes that the formation of the hydroxyhydrocarbonate in a soln. of magnesium carbonate in carbonic acid, when the partial press. of the carbon dioxide is low enough, is due to hydrolysis: $\text{Mg}(\text{HCO}_3)_2 + \text{H}_2\text{O} = \text{Mg}(\text{OH})(\text{HCO}_3) + \text{H}_2\text{CO}_3$. When this compound is boiled with water, two actions take place simultaneously: $\text{Mg}(\text{HCO}_3)\text{OH} \cdot 2\text{H}_2\text{O} = \text{Mg}(\text{HCO}_3)\text{OH} + 2\text{H}_2\text{O}$; and $\text{Mg}(\text{HCO}_3)\text{OH} + \text{H}_2\text{O} = \text{Mg}(\text{OH})_2 + \text{H}_2\text{O} + \text{CO}_2$, so that the product is a mixture of magnesium hydroxide and hydroxycarbonate. The change is slow because a coating of magnesium hydroxide protects the interior of the crystals from the water.

Needle-like crystals of the trihydrate were obtained by W. A. Davis. According to F. A. Genth and S. L. Penfield, the natural salt belongs to the rhombic system with axial ratios $a : b : c = 0.6450 : 1.04568$; and their values for the specific gravity of nesquehonite range from 1.83 to 1.852; H. Leitmeier gave 1.854; and for the artificial crystals, G. von Knorre gave 1.808, and H. Beckurts, 1.875. Well-developed crystals of magnesite are rare. R. W. G. Wyckoff tried to get Laue's patterns with some short six-sided prisms, but the results were not satisfactory. X-radiograms of the powder by W. P. Davey and E. O. Hoffman showed that the space lattice is like that of sodium chloride. A. W. Hull also studied the subject. According to F. A. Genth and S. L. Penfield, the hardness of the mineral is $2\frac{1}{2}$; and the indices of refraction for Na-light are $\mu_\alpha = 1.495$, $\mu_\beta = 1.501$, and $\mu_\gamma = 1.526$. P. Pascal gave 727×10^{-7} for the mol. coefficient of magnetization.

J. Fritzsche said the crystals are stable in air; and J. J. Berzelius said the crystals effloresce in dry air. Observations on the solubility of the salt are indicated below. The crystals were found by E. Soubeiran to have an alkaline taste, and to colour a decoction of violets green. H. Beckurts said the salt loses 15.27 per cent. of water and carbon dioxide at 100° —H. Rose assumed that water alone was lost at this temp.—at 200° more water and carbon dioxide are given off; and at 300° , all these gases have not been driven off; but all can be driven off at a higher temp. leaving residual magnesium oxide. J. J. Berzelius, and E. Soubeiran found the soln. gives off carbon dioxide when boiled, and deposits *magnesia alba*; H. Rose also noted the loss of carbon dioxide when the soln. is boiled, although J. Fritzsche found boiling water did not decompose the salt. J. J. Berzelius, and A. Bineau observed that when cold water dissolves the trihydrate a basic salt is precipitated and an acid salt remains in soln. According to V. A. Jacquelin, the salt loses carbon dioxide in a stream of moist air, or at 90° or 100° in a stream of water vapour.

C. Kippenberger prepared what he regarded as pentadecatetritahydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, by dissolving freshly precipitated magnesium carbonate in an aq. soln. of potassium or sodium hydrocarbonate, and allowing the soln. to stand for some time. The crystals are said to pass readily into the trihydrate, on standing in dry air, or over sulphuric acid. J. C. G. de Marignac obtained fine prismatic crystals of tetrahydrated magnesium carbonate, $\text{MgCO}_3 \cdot 4\text{H}_2\text{O}$, by very slowly evaporating a soln. of magnesium hydrocarbonate. The crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 1.6366 : 1.09653$, and $\beta = 101^\circ 33'$. A. Damour obtained the same product, but E. A. Nørgaard supposed it to be a mixture and not a chemical individual, even though J. C. G. de Marignac's analysis of an isolated crystal gave numbers in agreement with $\text{MgCO}_3 \cdot 4\text{H}_2\text{O}$.

J. Fritzsche found that when a sat. soln. of magnesium carbonate in carbonic acid is exposed to the cold of winter in a loosely covered vessel, a mixture of tri- and pentahydrated magnesium carbonate, $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$, is formed, and the proportion of the higher hydrate increases the lower the temp. of formation. E. A. Nørgaard prepared the pentahydrate by adding normal sodium carbonate to a soln. of magnesium sulphate at 0° until it begins to appear turbid, and allowing the mixture to stand for some time. G. Moressée dissolved magnesium oxide in water at 10° , sat. with carbon dioxide under a press. of 5–6 atm. The filtrate deposits

monoclinic crystals of the pentahydrate; the analyses sometimes show a somewhat higher percentage of magnesia, presumably owing to a partial decomposition.

The mineral *lansfordite* was reported by F. A. Genth and S. L. Penfield, from the anthracite mines of Nesquehoning, Lansford, Pa., where it has probably been formed by the percolation of ground waters rich in magnesia and carbon dioxide. Lansfordite occurs in prismatic crystals which were stated to belong to the triclinic system, the axial ratios being $a:b:c=0.5493:1:0.5655$. The chemical analysis corresponds with $3\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 21\text{H}_2\text{O}$. H. J. Brooke gave for the axial ratios of the monoclinic tabular crystals of the pentahydrate $a:b:c=1.1156:1:1.7817$, and $\beta=107^\circ 40'$, but there appears to be some mistake here. The crystals of the pentahydrate obtained by G. Moressée were found by G. Cesaro to be hexagonal prisms belonging to the monoclinic system with axial ratios $a:b:c=1.6393:1:0.96676$, and $\beta=77^\circ 50' 58''$; and the latter claimed that the crystalline form of the pentahydrate is identical with that of lansfordite, and that the smaller proportion of carbon dioxide in the analysis of lansfordite is really due to the decomposition of the unstable mineral during analysis. The sp. gr. of lansfordite was found to vary from 1.692 to 1.540; H. Leitmeier gave 1.688, and he also concluded that lansfordite is really partially decomposed pentahydrated magnesium carbonate, and that the crystallographic data of F. A. Genth and S. L. Penfield were defective owing to the imperfections in the specimen available for measurement. G. Cesaro gave 1.73 (19°) for the sp. gr. of the pentahydrate, and he stated that the crystals are harder than gypsum, but softer than calcite; F. A. Genth and S. L. Penfield gave $2\frac{1}{2}$ for the hardness of lansfordite.

According to E. A. Nørgaard, there are two forms of the pentahydrate—tabular and columnar. The former is produced below 16° , the latter below 10° . J. Fritzsche found the crystals of the pentahydrate part with two-fifths of their combined water when exposed to air, and more rapidly on exposure to sunlight; the same result is obtained by keeping the pentahydrate for a long time in water at 50° ; and when heated to 75° , they lose carbon dioxide as well as water. E. A. Nørgaard said that the tabular crystals pass into the trihydrate if heated under water at 20° – 25° ; and when warmed under water to about 100° , they begin to lose carbon dioxide provided contact with the walls of the vessel is avoided; if the temp. be raised slowly, the pentahydrate swells at about 50° , and passes into the trihydrate; if the temp. be raised very rapidly to 90° , the tabular crystals pass into the monohydrate. The columnar crystals effloresce on exposure to air, and decompose when boiled in water more readily than the tabular crystals. The solubility of the pentahydrate is indicated in the next section. According to G. Cesaro, the aq. soln. is alkaline to litmus and phenolphthalein, and he found that the residue obtained by the spontaneous evaporation of its aq. soln. seems to contain both the original substance and a small quantity of nesquehonite, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$. A soln. of G. Moressée's carbonate becomes turbid when heated to boiling, but the precipitate redissolves on cooling the liquid to 10° , and the latter, when evaporated, leaves an amorphous residue containing crystals of both $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$ and of nesquehonite. H. Leitmeier found the heating curve of the pentahydrate to show a well-defined break at about 50° corresponding with its transformation into the trihydrate. The tetrahydrate of J. C. G. de Marignac gives no such break.

§ 16. The Solubility of Magnesium Carbonate

The available data for the solubility of normal magnesium carbonate in water are not satisfactory. T. Bergman¹ made some observations on this subject in 1775. P. Butini found that "an ounce of distilled water dissolves from 1.0 to 1.5 grains of magnesia, whereas the same quantity of aerated water takes up 13 grains." According to A. M. Pleischl, and M. Pichard, when powdered magnesite is moistened with water, it gives an alkaline reaction with vegetable colouring matters. N. Ljubavin reported that at 26°, 100 grms. of water dissolve 0.27 grm. of normal magnesium carbonate, and 8.12 grms. of trihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$; on the other hand, W. A. Davis stated that magnesite and dolomite are as resistant to the solvent action of water as is calcium carbonate. Magnesite is insoluble in water, and is not affected to an appreciable extent by boiling it with water or with an aq. soln. of an alkali carbonate. F. Gothe says water free from carbon dioxide dissolves 94.4 mgrms. of magnesium carbonate per litre; and R. C. Wells, that a soln. of distilled water in equilibrium with atm. air, at 20°, dissolves 0.083 mgrm. of magnesite. The diversity of the data indicated below has been explained by assuming the existence of various modifications of magnesium carbonate which slowly pass into stable forms.

The anhydrous magnesium carbonate prepared by R. Engel by heating to 130° double ammonium magnesium carbonate, is sensitive towards water, for it slakes in moist air, and readily forms the trihydrate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$; 100 c.c. of water was also found to dissolve 0.2 grm. of the carbonate. According to E. A. Nörgaard, 100 parts of water, between 0° and 7°, dissolve about 0.167 part of both forms of the pentahydrate, $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$; and, according to G. Cesaro, 100 parts of cold water dissolve 0.374 of the pentahydrate prepared by G. Moressée. A. Bineau, R. Engel, and H. Beckurts noted the solubility of the trihydrate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, in water, and E. A. Nörgaard found that 100 grms. of soln. between 0° and 16°, contained:

	0°	6.5°	8°	16°	15°	25°	35°
$\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$	0.15	0.153	0.155	0.179;	0.141	0.129	0.105 grm.

The data between 15° and 35° are by F. Auerbach. F. Kohlrausch and F. Rose did not get constant results by measuring the conductivity of sat. soln., but later F. Kohlrausch obtained 794×10^{-6} rec. ohms for the sp. conductivity of a soln. sat. at 18°. According to E. Soubeiran, when an aq. soln. of magnesium carbonate is boiled, carbon dioxide is evolved, and *magnesia alba* is precipitated. A. Cavazzi showed that while the dissociation of calcium carbonate in boiling water is limited when a certain proportion of calcium hydroxide has been dissolved, no limit occurs with the dissociation of magnesium carbonate under these conditions—magnesium hydroxide is a weak base nearly insoluble in water, while calcium hydroxide is a strong base fairly soluble in water; the former, too, has little affinity for carbon dioxide, while the latter has a strong affinity for that gas.

N. Ljubavin observed that the solubility of magnesium carbonate in water is augmented by the presence of calcium chloride, or of sodium chloride. R. C. Wells also studied the solubility of magnesium carbonate in natural waters. E. Fleischer

found an aq. soln. of calcium sulphate readily decomposes magnesium carbonate, particularly if some sodium chloride is present. According to F. K. Cameron and A. Seidell, in air free from carbon dioxide, the solubility of magnesium carbonate increases to a maximum and then decreases with increasing conc. of sodium chloride; thus, expressing the results in grams per litre, at 23°:

NaCl	.	.	0.0	28.0	59.5	106.3	147.4	231.1	272.9	331.4
MgCO ₃	.	.	0.176	0.418	0.527	0.585	0.544	0.460	0.393	0.293

but, when in contact with an atm. of carbon dioxide, under normal press., the solubility of magnesium carbonate decreases regularly with increasing conc. of sodium chloride.

NaCl	.	.	7.0	56.5	119.7	163.9	224.8	306.6
MgCO ₃	.	.	30.64	30.18	27.88	24.96	20.78	10.75

F. K. Cameron and A. Seidell added: "This appears to be a real exception to the hypothesis of electrolytic dissociation for which no explanation based upon that hypothesis can be offered." C. Kippenberger explains the phenomenon by assuming that the products of a reaction between the two salts suffer hydrolysis. The solubility of magnesium carbonate in soln. of sodium sulphate, at 24°, has been measured by F. K. Cameron and A. Seidell. In an atm. free from carbon dioxide, the solubility increases with increasing conc. of sodium sulphate:

Na ₂ SO ₄	.	.	0.00	25.12	54.76	95.68	160.8	191.9	254.6	305.1
MgCO ₃	.	.	0.216	0.586	0.828	1.020	1.230	1.280	1.338	1.388

The solubilities at 35.5° are less, showing that the solubility of magnesium carbonate in soln. of sodium sulphate, with soln. exposed to an atm. of carbon dioxide, under normal press., increases slightly and then decreases with increasing conc. of sodium sulphate. W. A. Davis found the presence of potassium sulphate, potassium nitrate, or potassium chloride favours the soln. of magnesium carbonate, and he believes the increased solubility is due to the formation of mixed salts, KSO₄.Mg.CO₃K; NO₃.Mg.KCO₃; Cl.Mg.KCO₃, etc. According to F. Gothe, the solubility of magnesium carbonate is increased by the presence of alkali chlorides, nitrates, and sulphates in the water, but decreased by alkali carbonates, and by the alkaline earth chlorides, nitrates, and sulphates; ammonium salts decompose the carbonate and the effect on the solubility cannot be determined. The solubility is increased when the water contains organic (humus) substances, especially when alkali salts are also present, but is decreased in the presence of alkali-earth salts. According to R. C. Wells, certain natural waters, freely exposed to the atm., seem to be super-saturated with respect to magnesite, but none of them approaches very closely to the point of sat. of the trihydrate. A. Frébault and A. Destrem have studied the action of disodium hydrophosphate on magnesium carbonate. G. C. Wittstein found magnesium carbonate is readily soluble in cold soln. of the alkali borates, and when heated, the soln. forms a precipitate which redissolves on cooling.

Freshly precipitated magnesium carbonate is soluble in soln. of magnesium chloride or magnesium sulphate. According to E. A. Nørgaard, the solubility of magnesium carbonate is raised in the presence of magnesium sulphate, and with a mol of the latter salt per litre,

			0°	10°	20°	30°
MgCO ₃	.	.	0.20	0.15	0.11	0.18 mol.

T. S. Hunt was able to dissolve 5 grms. of magnesium carbonate in a litre of water containing 60 grms. of heptahydrated magnesium sulphate and a little sodium chloride; when the alkaline soln. is heated a precipitate is formed which redissolves as the soln. cools. According to E. A. Nørgaard, freshly prepared tabular crystals of pentahydrated magnesium carbonate, dissolve in a 4 per cent. soln. of magnesium

sulphate or sodium carbonate, but the prismatic form is insoluble in these menstrua.

W. A. Davis supposes a mixed salt of the type $\text{Mg} \begin{smallmatrix} \text{SO}_4 \\ \text{CO}_3 \end{smallmatrix} \text{Mg}$ is formed.

According to C. Kippenberger, soln. of *sodium carbonate* readily dissolve freshly precipitated magnesium carbonate. F. K. Cameron and A. Seidell found for soln. in equilibrium with an atm. free from carbon dioxide at 25°, when the results are expressed in grams per litre,

Na_2CO_3 . .	0.00	23.12	50.75	86.42	127.3	160.8	181.9	213.2
MgCO_3 . .	0.223	0.288	0.510	0.879	1.314	1.636	1.972	2.317

Except for the lower conc., the increase in solubility of the magnesium carbonate with increase in the amount of sodium carbonate is represented by an approximately straight line. The sp. gr. of the soln. were also determined. F. Auerbach found at 15°, 25°, and 35° for soln. of *potassium hydrocarbonate*, when the results are expressed in mols per litre, at 25°:

KHCO_3 . .	0	0.0985	0.2210	0.3434	0.4985	0.3906	0.5893	0.6406	1.125
MgCO_3 . .	0.0087	0.0115	0.0149	0.0181	0.0217	0.0196	0.0128	0.0117	0.0061

Solid phases

$\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$

$\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$

The solubility thus increases as the conc. of the alkali hydrocarbonate increases until the double salt, $\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$, is formed, and thereafter the solubility diminishes. The solubility of *magnesia alba* was found by P. Butini,² T. Bergman, C. L. Berthollet, and F. Gothe to be raised by the presence of *carbon dioxide* in soln. A similar remark applies to magnesium carbonate.

P. Butini stated that water may be over-saturated with *magnesia* and yet pass through the filter-paper and remain clear; such a soln. is obtained by immediately filtering the water in which epsom salt has been decomposed; and if heated to 20° (which may be done in the palm of the hand), it lets fall its earth, which is redissolved when the liquid cools to about 15°. This is a very amusing experiment.

According to E. Soubeiran, the sat. soln. contains twice as much carbon dioxide as the normal carbonate. It was assumed by A. Cossa, C. Kippenberger, etc., that **magnesium hydrocarbonate**, $\text{Mg}(\text{HCO}_3)_2$, is formed, but the salt has not been isolated; and, according to F. P. Treadwell and M. Reuter, the hydrocarbonate exists in aq. soln. only in the presence of a large excess of carbon dioxide; if the partial press. of this gas falls below 2 per cent., the soln. loses all its free carbon dioxide and part of that present as hydrocarbonate. At 15°, a litre of a soln. is estimated to contain 1.9540 grms. of hydrocarbonate, and 0.7156 gm. of carbonate. The conclusion is supported by R. Rinne; and P. N. Raikow found that a soln. of magnesium nitrate precipitated by a definite amount of potassium hydroxide, absorbed enough carbon dioxide to form the hydrocarbonate. M. Monhaupt tried to precipitate the hydrocarbonate by adding alcohol to the sat. soln., but he obtained only the trihydrated carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$. W. A. Davis also found that the solid phase which separated from a soln. of the so-called hydrocarbonate is trihydrated magnesium carbonate, a result confirmed by F. K. Cameron and W. O. Robinson. The latter also measured the vap. press. of carbon dioxide, expressed in *p* cms. of mercury, when *w* grms. of carbon dioxide are successively added to wet magnesium hydroxide:

<i>w</i> . .	0.00	0.1519	0.1953	0.2170	0.3038	0.3255	0.3906	0.5642
<i>p</i> . .	76	78	80	88	90	112	142	275

The results are plotted in Fig. 28, which shows a curve consisting of three parts. The portion *AB* remains constant, and it corresponds with the formation of normal magnesium carbonate; the portion *BC* corresponds with the absorption of carbon dioxide—some of the solid phase appeared to pass into soln.; and the portion *CD* in which the addition of carbon dioxide has no influence on the solid phase. When the excess of carbon dioxide is allowed to escape until *p* has reached atm. press.,

the molar ratio $\text{MgO} : \text{CO}_2$ in the solid is nearly that required for the hydrocarbonate. F. K. Cameron and W. O. Robinson regard the solid as a soln. of carbon dioxide in trihydrated magnesium carbonate. The soln. of magnesium carbonate in carbonic acid containing "13 grains per ounce" is the *fluid magnesiae* or the *liquor magnesiae carbonates* of the British Pharmacopœia.

H. Leitmeier found a litre of water sat. with carbon dioxide at ordinary temp. dissolves 0.08 gm. of crystalline magnesite, and 0.22 gm. of amorphous magnesite. The solubility of magnesium carbonate in aq. soln. of carbon dioxide depends on the slowness of the conversion of one modification into another—say, the basic carbonate into trihydrated normal carbonate—and this, in turn, depends on the source of the solid employed, and on the time of contact. Thus, R. Engel found the following values for the solubilities starting with different materials, and after the elapse of different periods of time :

Time in hrs.	Magnesium oxide.	Trihydrated normal carbonate.	Hydrocarbonate.
0.15	3.5	4.3	1.25
1.00	6.4	6.4	2.50
1.30	6.4	6.4	3.75
9.00	6.4	6.4	5.00

Before the importance of this was recognized, the results were very discordant ; thus, a litre of water sat. with carbon dioxide was found by J. R. von Wagner, and G. Merkel to dissolve 1.31 grms. of magnesium carbonate ; H. Beckurts, 8.39 grms. ; and A. Bineau, 23.3 grms. R. Engel and J. Ville give for the solubility of magnesium carbonate, in grams per litre, in water at 19.5° , sat. with carbon dioxide at various press. expressed in atm. :

CO_2	1	2.1	3.2	4.7	5.6	6.2	7.5	9.0	atm.
MgCO_3	25.79	33.11	37.30	43.50	45.20	48.50	51.20	56.59	

They also gave for the solubility of magnesium carbonate in water sat. with carbon dioxide at various temp. at a press. of one atm., when the results are expressed in grams per litre :

	13.4°	19.5°	29.3°	46.0°	62.0°	70.0°	82.0°	90°	100°
MgCO_3	28.45	25.79	21.95	15.7	10.35	8.1	4.9	2.4	0.0

T. Schlösing represented the solubility of magnesium carbonate in water at different press. p of carbon dioxide, by the empirical formula $p^{0.362} = 0.0398y$, where y denotes the amount of magnesium hydrocarbonate in the soln. expressed in grams per litre. R. Engel obtained good results with the empirical formula $p^{0.333} = 0.814y$, i.e. with $y = 1.934\sqrt[3]{p}$, or, at a definite temp., the quantity of magnesium carbonate dissolved by water with carbon dioxide in soln., is proportional to the cube root of the press. of the carbon dioxide.

G. Bodländer attempted to obtain a formula of the same form as that employed to represent the solubility of calcium carbonate in water containing carbon dioxide, but he found it necessary to assume the presence of ions in soln. of the form $\{(\text{MgCO}_3)_n\text{MgOH}\}$. F. P. Treadwell and M. Reuter have also shown that, at the lower conc., there is less carbon dioxide in soln. than corresponds with the formula $\text{Mg}(\text{HCO}_3)_2$, a conclusion which was confirmed by R. Rinne. In the opinion of J. Johnston, the results of F. P. Treadwell and M. Reuter, and of J. W. Leather and J. N. Sen on the ternary system, $\text{MgCO}_3 - \text{H}_2\text{CO}_3 - \text{H}_2\text{O}$, and the quaternary system, $\text{CaCO}_3 - \text{MgCO}_3 - \text{H}_2\text{CO}_3 - \text{H}_2\text{O}$, are vitiated by defective analyses or by the

FIG. 28.—Pressure of Carbon Dioxide over Magnesium Hydroxide.

uncertainty whether equilibrium was really attained. J. Johnston calculated the solubility product, at 18° , to be $[\text{Mg}^{++}][\text{CO}_3^{--}] = 1.2 \times 10^{-4}$, or else $[\text{Mg}^{++}][\text{OH}]^2 = 1.2 \times 10^{-11}$.

According to J. Johnston, (1), $[\text{Mg}^{++}][\text{CO}_3^{--}] = K$; (2), $[\text{H}_2\text{CO}_3] = k'[\text{CO}_2] = c'p$, where p is the partial press. of the carbon dioxide; (3), $[\text{H}^+][\text{HCO}_3^-] = k_1[\text{H}_2\text{CO}_3]$; (4), $[\text{H}^+][\text{CO}_3^{--}] = k_2[\text{HCO}_3^-]$; (5), $[\text{H}_2\text{CO}_3] = nk[\text{CO}_2] = ncp$, where $c = a/22.4$, and n , from the work of J. Walker and W. Cormack on the proportion of the total carbon dioxide in soln. existing as H_2CO_3 , is greater than 0.5. By dividing (3) by (4), it follows (6), $[\text{HCO}_3^-]^2/[\text{CO}_3^{--}][\text{H}_2\text{CO}_3] = k_1/k_2 = r$; and when combined with (5), there remains (7), $[\text{HCO}_3^-]^2/[\text{CO}_3^{--}]cp = nr$. Consequently, (8), $[\text{Mg}^{++}][\text{HCO}_3^-]^2 = nrKcp$, or $nrK = [\text{Mg}^{++}][\text{HCO}_3^-]^2/cp$; (9), $[\text{OH}^-]/[\text{HCO}_3^-] = K_w/nk_1cp$, where K_w is the constant for water; (10), $[\text{OH}^-]^2/[\text{CO}_3^{--}] = K_w^2/nr_1K_2cp$. At 18° , for partial press. ranging from 0.0002 to 0.0005 atm., J. Johnston calculated from R. Engel's measurements (7), $nrKcp = 229.6p$; (8), $nrKcp = 2.755 \times 10^{-2}p$; (9), $K_w/nk_1cp = 4.012 \times 10^{-7}p$; (10), $K_w^2/nk_1k_2cp = 3.694 \times 10^{-11}p$; and either (11), $[\text{Mg}^{++}][\text{CO}_3^{--}] = K = 1.2 \times 10^{-4}$; or (12), $[\text{Mg}^{++}][\text{OH}]^2 = 1.2 \times 10^{-11}$. By combining (1) and (10), or (8) and (9), it follows that at 18° $[\text{Mg}^{++}][\text{OH}]^2 = 4.433 \times 10^{-15}/p$, a value which exceeds (12) when p is less than 0.000369.

When $p < 0.000369$, at 18° , the solid phase is not $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, but $\text{Mg}(\text{OH})_2$. At the transition press. 0.000369, both solid phases are in equilibrium. If the press. of the carbon dioxide is kept constant at p atm., and water be evaporated from the soln. so slowly at 18° that equilibrium conditions are continuously maintained, the following amounts of magnesium hydroxide, or trihydrated carbonate, will be obtained (grams per litre):

p	0	0.00030	0.00035	0.00040	0.00045	0.00050 atm.
Total $[\text{Mg}]$	0.00015	0.1934	0.02486	0.02742	0.02868	0.02924
Grms.	0.0087	1.13	1.45	1.60	3.97	4.05
		$\text{Mg}(\text{OH})_2$			$\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$	
					4.12	0.02976 mols

The transition press. increases rapidly with temp. because K_w^2/nk_1k_2 increases rapidly whilst K/c varies but little; the increase cannot be calculated because the rate of change of k_2 with temp. is not known.

It follows, adds J. Johnston, that the ordinary methods of preparing magnesium carbonate (in which, it is safe to say, a state of equilibrium is not attained continuously) will yield a product contaminated with hydroxide, the amount of which will depend upon the mode of working generally, and upon the prevailing partial press. of CO_2 over the liquid in particular; moreover, that this contamination can be avoided completely by working with a partial press. p greater than a certain limit.

J. Johnston continues: In soln. sat. with both calcium and magnesium carbonates, the ratio of the conc. of Mg^{++} and Ca^{++} must have a definite value; thus, at 16°

$$\frac{[\text{Mg}^{++}]}{[\text{Ca}^{++}]} = \frac{[\text{Mg}^{++}][\text{CO}_3^{--}]}{[\text{Ca}^{++}][\text{CO}_3^{--}]} = \frac{K_{\text{Mg}}}{K_{\text{Ca}}} = \frac{1.4 \times 10^{-4}}{1 \times 10^{-8}} = 14,000$$

Hence, if a soln. of the two carbonates in carbonic acid is evaporated, or if the partial press. of the carbon dioxide be gradually reduced, at 16° , calcium carbonate will be precipitated so long as the above ratio is less than 14,000, as would normally be the case in natural waters when the press. of the carbon dioxide is sufficient to prevent the precipitation of magnesium hydroxide. The order of precipitation will be reversed if the relative conc. of the magnesium ions be greater than 14,000, as could be the case when a soluble magnesium salt is present. These deductions are valid when CaCO_3 and $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ are the only solid phases which separate; if a solid soln. of the two be formed at certain conc., these deductions would have to be modified accordingly. If the partial press. of carbon dioxide is such that magnesium hydroxide may precipitate, it follows that:

$$\frac{[\text{Mg}^{++}]}{[\text{Ca}^{++}]} = \frac{[\text{Mg}^{++}][\text{OH}]^2}{[\text{Ca}^{++}][\text{OH}]^2} = \frac{1.2 \times 10^{-11}p}{3.43 \times 10^{-19}} = 3.5 \times 10^7 p$$

a ratio which decreases steadily as p is reduced. Hence calcium carbonate precipi-

tated from a soln. containing magnesium may be very readily contaminated with appreciable proportions of magnesium hydroxide, which would be removed only slowly by repeated re-precipitations. J. C. Hostetter, for example, has emphasized how difficult it is to get calcium carbonate free from magnesia. This difficulty may be obviated very easily, namely, by conducting the operations in such a way that the liquid is always sat. with CO_2 at a press. above a certain limiting value; this limit, which increases with the temp., cannot at present be specified very accurately, but is in all probability not greater than 1 atm. for any conditions likely to be encountered in actual practice.

According to C. L. Berthollet, the soln. of magnesium carbonate has a bitter taste, and an alkaline reaction, and C. H. Pfaff, A. M. Pleischl, and C. L. Berthollet stated that the alkalinity towards vegetable colouring matters—tincture of logwood, tumeric, red litmus, etc.—is maintained even when a great excess of carbon dioxide is in soln., but, according to the last-named, the soln. gives a green colour with tincture of violets, and he also stated that the soln. becomes turbid when heated to 75° , but recovers its transparency on cooling. According to J. J. Berzelius, and J. Fritzsche, when the soln. is heated to 50° , or, according to E. Soubeiran, when evaporated in vacuo, trihydrated normal carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, is deposited. According to W. Weldon, and E. Bohlig, when sodium chloride is added to a sat. soln. of magnesium carbonate and carbon dioxide, sodium hydrocarbonate is precipitated, and magnesium chloride remains in soln.

Magnesite is not quickly attacked by cold *hydrochloric acid* or *sulphuric acid*, but it dissolves readily in the warm acids. According to K. Haushofer, and A. Vesterberg, compact magnesite is more quickly dissolved by *acetic acid* than crystallized magnesite; and the solubility of crystallized magnesite decreases with increasing conc. of the acid. A. Vesterberg, and T. S. Hunt found that magnesite dissolves more slowly than dolomite in acetic acid; K. Haushofer came to the opposite conclusion. F. W. Pfaff found that powdered magnesite is very slightly soluble in a soln. of *hydrogen sulphide* in water; and its solubility in an aq. soln. of *ammonium sulphide* is small. L. Naudin and F. de Montholon have studied the action of hydrogen sulphide on magnesite suspended in water. J. A. Hedvall and J. Heuberger found the reaction temp. and the thermal value of the reaction between magnesium carbonate and *calcium oxide* to be respectively 300° and 2.5 Cals.; with *strontium oxide*, 240° and 11.5 Cals.; and with *barium oxide*, 230° and 19 Cals.

§ 17. The Basic Magnesium Carbonates—Magnesium Oxycarbonates

A considerable number of distinct basic magnesium carbonates have been reported:

Representing the proportions of $\text{MgO} : \text{CO}_2 : \text{H}_2\text{O}$ by numerals in that order, J. Fritzsche¹ prepared the (1), 3 : 2 : 3-carbonate; also the (2), 4 : 3 : 4-carbonate; H. Rose the (3), 4 : 3 : 7-carbonate; J. J. Berzelius, the (4), 4 : 3 : 8-carbonate; J. Fritzsche and H. Rose, the (5), 5 : 4 : 5-carbonate; H. Rose, the (6), 5 : 4 : 6-, (7), 5 : 4 : 7-, (8), 5 : 4 : 8-, and (9), 5 : 4 : 9-carbonates; H. Rose, and V. A. Jacquelin (10), 5 : 4 : 10-carbonate; H. Rose (11), 5 : 4 : 11-, and (12), 5 : 4 : 12-carbonate; G. Kittel (13), 5 : 4 : 16-carbonate; H. Beckurts (14), 7 : 5 : 9; H. Rose (15), 6 : 4 : 6-carbonate, and V. A. Jacquelin (16), 6 : 5 : 14-carbonate. There are also the native basic carbonates 2 : 1 : 3; 2 : 1 : 4; 4 : 3 : 3; and 4 : 3 : 4; and the anhydrous basic carbonates. With $\text{MgO} : \text{CO}_2$, viz. 10 : 9; 9 : 8; 8 : 7; 7 : 6; 6 : 5; 5 : 4; and 9 : 7-carbonates.

This confusing variety of the basic magnesium carbonates is usually regarded as a consequence of the more or less incomplete hydrolysis of the normal carbonate; and this view can be traced back to H. Rose's work in 1851-2, *Ueber den Einfluss des Wassers bei chemischen Zersetzungen*, whereby it was shown that water acting as a weak acid is able to decompose more or less completely the salts of the weak carbonic acid. Indeed, said M. Roloff,

Die Zusammensetzung des Gemisches ist dabei von den zufälligen Nebenumständen abhängig; die bestimmte Formel eines basischen Karbonates aufzustellen ist daher von vornherein aussichtslos.

The *magnesia alba* of pharmacy is a basic carbonate of very indefinite composition; it is obtained by precipitating soln. of the sulphate, chloride, or nitrate with alkali carbonate. A soln. of magnesium sulphate may be employed, also many mineral waters, salt springs, or the mother liquor of sea-water. If these liquids likewise contain calcium salts these must be first removed by adding an alkali sulphate to the liquid. E. Durand, and E. Schmidt have described the preparation of *magnesia alba* in detail. W. Esch made it by the action of ammonia and carbon dioxide on a paste made of water and calcined magnesia. F. Oswald described the preparation from the mineral waters at Bilin; H. Endemann from the residue remaining after the calcination of magnesite for its carbon dioxide. For the preparation from dolomite, *vide supra*.

The light white powder obtained by mixing soln. of 10 parts of magnesium sulphate and 12 parts of sodium carbonate crystals, each dissolved in 80 parts of water; boiling for 15 mins.; washing; draining; and drying, is the so-called *light magnesium carbonate*, or the *magnesi carbonas levis* of the pharmacopœia. Under

the microscope it consists of amorphous granules and slender prismatic crystals. In the preceding operations, if 20 instead of 80 parts of water be employed; the mixture evaporated to dryness; the residue washed until all the soluble sulphate is removed; and dried, the resulting white granular powder is the *heavy magnesium carbonate*, or the *magnesi carbonas ponderosus* of the pharmacopœia. Both products are basic carbonates. W. C. Anderson's analyses of commercial samples of heavy carbonate correspond with 41 : 20 : 83, or approximately $\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$; of the light carbonate, 39 : 19 : 85, or approximately $\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\frac{1}{2}\text{H}_2\text{O}$; and of the so-called crystal carbonate, 24 : 14 : 85, or approximately $3\text{MgCO}_3 \cdot 2\text{Mg}(\text{OH})_2 \cdot 16\text{H}_2\text{O}$.

The mineral *hydromagnesite*, analyzed by T. Wachtmeister, F. von Kobell, J. L. Smith and G. J. Brush, G. C. Hoffmann, and G. Tschermak, is a basic magnesium carbonate with a composition 4 : 3 : 4, or $3\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$ —a kind of native *magnesia alba*. J. D. Dana considered the crystals belonged to the monoclinic system, with axial ratios $a : b : c = 1.0379 : 1.04652$, and $\beta = 90^\circ$. E. Weinschenk and P. Groth also place the crystals in the monoclinic system, but G. Tschermak and L. Brugnatelli favour the rhombic system. J. L. Smith and G. J. Brush found the sp. gr. of a sample from Texas to be 2.145–2.180; E. Weinschenk found with a sample from Lancaster, 2.32; and L. Brugnatelli found with a sample from Aostatal, 2.196–2.210. The latter also gave the index of refraction $\mu_\beta > 1.530$, and $\mu_\gamma > 1.538$. The hardness on Mohs' scale is $3\frac{1}{2}$. G. A. Young has reported on the large deposits of hydromagnesite near Atlin, British Columbia, where it occurs as a white soft mineral which falls to powder on drying. The so-called *lancasterite* of B. Silliman is considered by J. L. Smith and G. J. Brush to be a mixture of brucite and hydromagnesite. The amorphous mineral *giorgiosite* found by A. Lacroix at Vesuvius is a 4 : 3 : 3-carbonate, or $3\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$. The mineral *hydrogiobertite* found by E. Scacchi near Pollena (Vesuvius) has a composition corresponding with 2 : 1 : 3-carbonate, or $\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$. Its sp. gr. is 2.149 to 2.174; L. Brugnatelli's optical study of this mineral inclines him to the opinion that it is a mixture of at least two other minerals. F. Zambonini identified hydrogiobertite with hydromagnesite. L. Brugnatelli found monoclinic prismatic crystals of the Italian mineral *artinite*—named after E. Artini, at Val Brutta, Val Malenco, and Val Lanterna. Analyses correspond with the 2 : 1 : 3-carbonate, or $2\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$; its sp. gr. is 2.028 at 21.6° , and 2.013 at 22° ; and its hardness is about $2\frac{1}{2}$.

J. J. Berzelius showed that the composition of *magnesia alba* is influenced (i) *by the relative quantity of the precipitant*—if an excess of the alkali carbonate is used, the precipitate is more dense than when the magnesium salt is in excess; (ii) *by the concentration of the solutions*—the more conc. the two soln., the denser the precipitate, and the more normal carbonate does it contain; and (iii) *on the temperature*—the precipitate formed in the cold is lighter than when the soln. are warm, and the utmost degree of lightness is obtained by allowing the precipitate to freeze while still moist. J. J. Berzelius continued: the precipitate formed in the cold approaches more nearly to the composition of the normal salt than that formed in hot soln.; at the same time, a quantity of magnesia remains in soln., because the normal salt is hydrolyzed by water into an insoluble basic salt, and a soluble acid salt. When heated, carbon dioxide is given off by the soln., and the greater part of the magnesia is precipitated from the soln., and the precipitate becomes more basic owing to the escape of carbon dioxide. The composition of the precipitate also depends on (iv) *the time the precipitate is in contact with the mother liquid*. J. J. Berzelius showed that when boiled for a long time, the precipitate has the composition $\text{MgO} : \text{CO}_2 : \text{H}_2\text{O} = 4 : 3 : 4$. According to J. Fritzsche, if moderately boiled, the precipitate is converted into the 5 : 4 : 4-carbonate, but if long boiled, it becomes mixed with a constantly increasing proportion of the 4 : 3 : 4 and the 3 : 2 : 3-carbonates. In general, it may be said that *every alteration in the conditions of preparation of magnesia alba tends to modify the composition of the product*. W. A. Davis found traces of alkali in the soln. caused "a wide variation in the results."

Analyses of *magnesia alba* have been made by J. Fritzsche, J. J. Berzelius, H. Rose, O. Brill, K. Kraut, H. Beckurts, E. A. Nörsgaard, W. C. Anderson, etc., and many of the results have been represented by chemical formulæ and assumed to be definite compounds without the application of any criterion as to whether

mixtures or individuals are in question. J. J. Berzelius favoured the formula 4 : 3 : 4 ; but J. Fritzsche and R. Rinne showed that while the original precipitate approaches 5 : 4 : 5 in composition, this by the prolonged action of boiling water approaches 4 : 3 : 4, and afterwards 3 : 2 : 3. G. Rose observed that the product obtained by evaporating the acid carbonate on a water-bath includes spherules of *magnesia alba* with crystals of the normal salt resembling aragonite. E. A. Nörsgaard failed to obtain a definite crystalline basic carbonate. L. Joulin argued that *magnesia alba* is a mixture of magnesium hydroxide and carbonate in proportions dependent on the conc., temp., and the relative proportions of the reacting salts. As previously indicated, W. A. Davis has shown that trihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, may be regarded as **dihydrated magnesium hydroxyhydrocarbonate**, $\text{Mg}(\text{HCO}_3)\text{OH} \cdot 2\text{H}_2\text{O}$, which is produced by the hydrolysis of a soln. of magnesium hydrocarbonate. The dihydrate is readily converted into anhydrous **magnesium hydroxyhydrocarbonate**, $\text{Mg}(\text{HCO}_3)\text{OH}$, as indicated in connection with trihydrated magnesium carbonate, where the preparation and properties of the hydroxycarbonates are therefore discussed. When the dihydrated hydroxycarbonate is suspended in boiling water, it slowly decomposes into magnesium hydroxide. The solid at any intermediate stage has a composition ranging between $\text{Mg}(\text{HCO}_3)\text{OH} \cdot 2\text{H}_2\text{O}$ and $\text{Mg}(\text{OH})_2$, and the mixed character of the product is evident from a microscopic examination of the mass. Excluding the hydroxycarbonate and its hydrate, W. A. Davis shows good reasons for believing that all the varieties of basic magnesium carbonate, *magnesia alba*, light, heavy, and crystal magnesium carbonates are not definite salts, but mixtures of the anhydrous and dihydrated magnesium hydroxycarbonates and hydroxide in varying proportions.

Hydromagnesite, and *magnesia alba*, decompose at a lower temp. than magnesite (*q.v.*) ; the latter decomposes into magnesium oxide and carbon dioxide at 300° . According to P. Kremers, a litre of water at 15° dissolves 0.197 part of *magnesia alba* ; and, according to A. Bineau, 0.10 part in cold or boiling water. According to A. M. Pleischl, the aq. soln. has an alkaline reaction. S. Merkel found that with a soln. of carbon dioxide in a litre of water and at different press. :

Press. of CO_2	1	2	4	5	6 atm.
MgO dissolved	1.314	1.344	7.46	9.09	13.1 grms.

so that the solubility increases with increasing press. of carbon dioxide when the temp. is constant. G. C. Wittstein found the solubility in water is much raised in the presence of ammonium nitrate, and, according to A. Vogel, in the presence of ammonium chloride. *Magnesia alba* does not dissolve so quickly after it has been heated to 100° ; according to A. Vogel, the sat. soln. does not become turbid on exposure to air or by boiling ; but it is precipitated by potassium hydroxide. *Magnesia alba* is readily soluble in acids. According to T. S. Hunt, *magnesia alba* precipitates calcium carbonate from its soln. in carbonated waters ; and G. Bauck found that when *magnesia alba* is boiled with a dil. soln. of calcium chloride the precipitate contains $\text{CaCO}_3 : \text{Mg}(\text{OH})_2$ in the mol. proportion 3 : 1. According to C. A. Gössmann, if carbon dioxide be passed into a soln. of sodium chloride containing calcium sulphate and *magnesia alba*, magnesium chloride, sodium sulphate, and calcium carbonate are formed. E. Fleischer digested eq. quantities of *magnesia alba*, calcium sulphate, and a soln. of sodium chloride (1 : 6) for an hour at 80° , and found 30 per cent. of the calcium sulphate was transformed into carbonate ; the change is less complete if the salt soln. be more dil., if some magnesium sulphate be present, and if the mixture be kept cold.

§ 18. Complex or Double Salts with Magnesium Carbonate

According to J. J. Berzelius,¹ an aq. soln. of magnesium nitrate or chloride, when mixed with an excess of sodium hydrocarbonate, furnishes crystals similar to those obtained when potassium hydrocarbonate is used as precipitant, and presumably misled by analogy, he assumed the crystals to be *sodium magnesium hydrocarbonate*, $\text{MgCO}_3 \cdot \text{NaHCO}_3 \cdot 4\text{H}_2\text{O}$. He added that the crystals are not so readily decomposed by water as the *potassium magnesium hydrocarbonate*, $\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$. H. St. C. Deville, J. Fritzsche, H. Rose, E. A. Nörgaard, and G. von Knorre did not succeed in verifying Berzelius' assumed sodium salt; nor did they obtain the tetrahydrate, $\text{Na}_2\text{CO}_3 \cdot \text{MgCO}_3 \cdot 4\text{H}_2\text{O}$. G. Mosander treated a warm soln. of a magnesium salt with an excess of sodium carbonate, and obtained a granular precipitate containing about 21 per cent. of sodium carbonate, and 79 per cent. of magnesium carbonate. The solid dissolved in water as a whole without separating the sodium salt, but, added J. J. Berzelius, if the compound be decomposed by ignition, the sodium salt may be leached out. The alkali magnesium carbonates are decomposed by water. K. Kippenberger mixed freshly precipitated magnesium carbonate with a soln. of sodium or potassium hydrocarbonate at ordinary temp., and found much magnesium carbonate dissolves, and crystallizes from the filtered soln. in about 24 hrs. The crystals approximate $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$. It is assumed that an alkali magnesium double carbonate is formed and afterwards decomposed.

G. Bollmann prepared what were regarded as hexagonal plates of **lithium magnesium tricarbonat**, $2\text{Li}_2\text{CO}_3 \cdot \text{MgCO}_3$, by dropping 4.6 c.c. of a 10 per cent. soln. of magnesium chloride into 100 c.c. of a sat. soln. of lithium carbonate. After the mixture has stood 4–6 weeks, the turbid soln. is clear, the hydrated magnesium carbonate has disappeared, and six-sided plates of this double salt appear. The crystals are but slowly decomposed by water. The crystals are hard enough to scratch glass.

H. St. C. Deville digested *magnesia alba* with an aq. soln. of sodium hydrocarbonate at 60°–70°, and obtained anhydrous **sodium magnesium carbonate**, $\text{Na}_2\text{Mg}(\text{CO}_3)_2$; G. von Knorre obtained the same salt by digesting trihydrated magnesium carbonate with an aq. soln. of sodium sesquicarbonate for 24 hrs. between 63°–65°, filtering the warm mixture, and washing well the solid. A. de

Schulten prepared the same compound by heating on a water-bath for 4-5 hrs. a mixture of soln. of 100 grms. of anhydrous sodium carbonate in 400 grmc. of water, and 20 grms. of magnesium nitrate in 50 grms. of water, rhombohedral or tetragonal crystals are formed which, he said, were uniaxial, and had a sp. gr. of 2.729 at 15°—G. von Knorre stated that his crystals were doubly refracting, and probably belonged to the tetragonal system. Both A. de Schulten and G. von Knorre agreed that the double salt is very slowly decomposed by cold water; and even at 100° the speed of decomposition is not fast. According to H. St. C. Deville, carbon dioxide and traces of water are lost when the crystals are ignited and the double salt is therefore assumed to be anhydrous. E. A. Nørgaard obtained the **pentadecahydrated sodium magnesium carbonate**, $\text{Na}_2\text{CO}_3 \cdot \text{MgCO}_3 \cdot 15\text{H}_2\text{O}$, in rhombic prismatic crystals, by cooling to a low temp. a soln. of magnesium sulphate made just turbid with sodium carbonate. The crystals are decomposed by water, and should be washed with the clear mother liquid and then pressed. *Magnesia alba* is formed when the crystals are boiled with water. Attempts made by H. St. C. Deville, E. A. Nørgaard, J. Fritzsche, H. Rose, V. A. Jacquelin, G. Kittel, K. Kippenberger, G. von Knorre, and G. Bollmann furnished a basic magnesium carbonate.

Crystals corresponding with **sodium magnesium chlorocarbonate**, $\text{NaCl} \cdot \text{Na}_2\text{CO}_3 \cdot \text{MgCO}_3$, were found by G. W. Leighton on the inside of an iron boiler in which the vapour of ammonium carbonate was passed through a lye containing sodium and magnesium chlorides; C. Winkler found them on the inside of the cooling apparatus of the Solvay soda process; and J. H. Pratt found them native at Borax Lake, San Bernadino County, Cal., and called the mineral *northupite*. A. de Schulten obtained the salt by heating a mixture of soln. of 15 grms. of magnesium chloride in 50 c.c. of water, and of 20 grms. anhydrous sodium carbonate and 150 of sodium chloride in 500 c.c. of water. The flocculent precipitate gradually forms regular octahedral crystals which are washed with the mother liquid, and dried at 100°. The crystals belong to the cubic system. C. Winkler represented the salt by the formula $\text{Na}_3(\text{MgCl})(\text{CO}_3)_2$, and S. L. Penfield and G. L. Jamieson, by

A. de Schulten gives 2.377 for the sp. gr. of the artificial crystals at 15°; and J. H. Pratt, 2.380 for northupite. The hardness of the mineral is 4. The crystals melt at a red heat, forming an enamel-like mass from which water extracts sodium carbonate and chloride, leaving magnesium oxide as a residue. J. H. Pratt gives 1.5117 for the index of refraction in Li-light; 1.5144 in Na-light; and 1.5180 in Ti-light. The crystals are stable in air, but slowly decomposed by cold or hot water.

The sodium and potassium magnesium carbonates are fundamentally different, so that H. St. C. Deville was led to say:

Dans aucun cas la soude et la potasse, dont les analogies sont si intimes, ne se séparent d'une manière plus complète que lorsqu'elles sont mises dans les conditions nécessaires pour former les mêmes carbonates double métalliques.

The double carbonates with rubidium, caesium, and thallium show more analogies. P. A. von Bonsdorff, and H. Rose treated a warm soln. of a magnesium salt with an excess of potassium carbonate, and obtained a precipitate which is slightly soluble in water, and separates from its soln. as a crystalline powder. If the soln. are mixed at the b.p., magnesium carbonate is alone precipitated. J. J. Berzelius prepared crystals of what were probably **tetrahydrated potassium magnesium carbonate**, $\text{K}_2\text{Mg}(\text{CO}_3)_2 \cdot 4\text{H}_2\text{O}$, by treating a cold aq. soln. of magnesium nitrate or chloride with an excess of potassium sesquicarbonate, and allowing the mixture to stand for a few days. H. St. C. Deville made small rhombic prisms of the same salt by digesting *magnesia alba* with an aq. soln. of potassium hydrocarbonate for 12 to

15 hrs. at 60° to 70° ; G. von Knorre prepared crystals of the salt by digesting 9 grms. of trihydrated magnesium carbonate and 50 grms. of potassium hydrocarbonate, with 50 c.c. of water for 21 hrs. at 60° to 70° , and by digesting 20 grms. of hexahydrated magnesium chloride and 40 grms. of potassium carbonate for two days at ordinary temp. If magnesium sulphate be used the precipitate is contaminated with sulphates. H. St. C. Deville found that the crystals are decomposed by cold water; and he gives for the axial ratios of the rhombic crystals $a : b : c = 0.7563 : 1 : 0.6068$.

J. J. Berzelius found that if an excess of potassium hydrocarbonate be added to a cold aq. soln. of magnesium chloride or nitrate, large crystals of **tetrahydrated potassium magnesium hydrocarbonate**, $\text{KHMg}(\text{CO}_3)_2 \cdot 4\text{H}_2\text{O}$, or $\text{Mg}(\text{KCO}_3)(\text{HCO}_3) \cdot 4\text{H}_2\text{O}$, are formed. In his study of the solubility of magnesium carbonate in soln. of potassium hydrocarbonate, F. Auerbach obtained the same salt. G. von Knorre made this salt by adding a very conc. soln. of 6 grms. of magnesium chloride to 50 c.c. of a soln. with 10 grms. of potassium hydrocarbonate, and 7 grms. of the normal carbonate—crystals are formed when the mixture is allowed to stand. R. Engel obtained this salt by the action of carbon dioxide on a soln. of potassium chloride and trihydrated magnesium carbonate; and the Salzbergwerk Neustassfurt has some patents on the subject.

In R. Engel's *magnesia-potash process*, magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, is suspended in a sat. soln. of potassium chloride, and the mixture sat. with carbon dioxide. A crystalline double salt, $\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$, separates from the soln.: $3(\text{MgCO}_3 \cdot 3\text{H}_2\text{O}) + 2\text{KCl} + \text{CO}_2 = \text{MgCl}_2 + 2(\text{KHCO}_3 \cdot \text{MgCO}_3 \cdot 4\text{H}_2\text{O})$. When the crystalline mass is treated with water at 140° under press., carbon dioxide is evolved, magnesium hydroxide is precipitated, and potassium carbonate remains in soln.: $2(\text{KHCO}_3 \cdot \text{MgCO}_3 \cdot 4\text{H}_2\text{O}) = \text{K}_2\text{CO}_3 + 2\text{Mg}(\text{OH})_2 + 7\text{H}_2\text{O} + 3\text{CO}_2$. Sodium carbonate cannot be formed in the same way since the corresponding sodium salt, $\text{MgCO}_3 \cdot \text{NaHCO}_3 \cdot 4\text{H}_2\text{O}$, does not precipitate.

According to J. C. G. de Marignac, the crystals belong to the triclinic system and have the axial ratios $a : b : c = 0.4261 : 1 : 0.5945$, and the axial angles $\alpha = 111^{\circ} 9'$, $\beta = 114^{\circ} 26'$, and $\gamma = 74^{\circ} 33'$. G. von Knorre gives for the sp. gr. 1.984 at 18° . J. C. G. de Marignac found the crystals to be stable in air. J. J. Berzelius added that the crystals are tasteless at first, but after a few seconds exhibit an alkaline flavour. When heated to 100° the crystals become opaque and lose water; and when strongly heated they soften and give off bubbles of carbon dioxide leaving a mixture of magnesium oxide and normal potassium carbonate. The crystals are soluble in water, but not without decomposition, for a basic magnesium carbonate is precipitated and a mixture of potassium hydrocarbonate and magnesium hydrocarbonate passes into soln. J. Fritzsche said that the precipitate is trihydrated magnesium carbonate mixed with the pentahydrate, and the proportion of the latter increases as the temp. of the water falls. G. von Knorre said that the salt is stable in water sat. with carbon dioxide.

R. Engel has investigated the conditions under which normal magnesium carbonate combines with potassium hydrocarbonate, and finds that for the same soln. of potassium hydrocarbonate the velocity of the reaction decreases as the temp. rises. If the temp. remains constant, the velocity increases with the initial conc. of the potassium soln. Combination ceases when it attains a certain limit, which is measured by the conc. of the soln. of the potassium salt remaining in contact with excess of magnesium carbonate without combining with it. This limit increases with the temp., and its variation is given by the formula $y = 2.5236 + 0.00517t + 0.003108t^2$, where y is the number of c.c. of standard sulphuric acid required to neutralize the carbonates remaining in soln. The product of the combination, $\text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$, is decomposed by water, and the decomposition tends towards a limit which is not identical with the limit of combination, but is always inferior to it by a quantity which is practically the same for all temp. P. Duhem regards this as an example where *la région des faux équilibres* separates two regions corresponding respectively to two reactions which are the inverse of one another.

The reaction was also investigated by E. H. Büchner, and he considers that R. Engel's systems were not in equilibrium, nor could M. Nanty confirm the existence of two distinct limits in the formation and decomposition of the system: $\text{KHCO}_3 + \text{MgCO}_3 \cdot 3\text{H}_2\text{O} + \text{H}_2\text{O} \rightleftharpoons \text{MgCO}_3 \cdot \text{KHCO}_3 \cdot 4\text{H}_2\text{O}$, at 20° – 30° ; since he found at the same temp. and press., the two reactions converge towards a common limit. F. Auerbach studied the conditions of stability as indicated in connection with the solubility of magnesium carbonate in soln. of potassium hydrocarbonate.

H. Erdmann and P. Köthner prepared **tetrahydrated rubidium magnesium hydrocarbonate**, $\text{MgRbH}(\text{CO}_3)_2 \cdot 4\text{H}_2\text{O}$, by heating on a water-bath at 60° in a current of carbon dioxide, a soln. of rubidium hydrocarbonate, and magnesium carbonate. The salt is very efflorescent. G. Bollmann prepared the same salt, and he also obtained microscopic rhombic plates of tetrahydrated **rubidium magnesium carbonate**, $\text{MgCO}_3 \cdot \text{Rb}_2\text{CO}_3 \cdot 4\text{H}_2\text{O}$, mixed with trihydrated magnesium carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, by adding rubidium carbonate to a well-cooled soln. of magnesium chloride. He likewise obtained tetrahydrated **caesium magnesium carbonate**, $\text{MgCO}_3 \cdot \text{Cs}_2\text{CO}_3 \cdot 4\text{H}_2\text{O}$. Both salts are readily decomposed by water. G. Bollmann also speaks of a possible *copper magnesium carbonate*.

According to A. F. de Fourcroy,² the addition of even a large excess of aq. ammonia to a soln. of a magnesium salt never precipitates more than half the magnesia present; and, according to N. J. B. G. Guibourt, one part of ammonium sesquicarbonate precipitates half the magnesium as carbonate from a soln. of two parts of magnesium sulphate; and two parts of ammonium sesquicarbonate precipitate all the magnesium as tetrahydrated **ammonium magnesium carbonate**, $(\text{NH}_4)_2\text{CO}_3 \cdot \text{MgCO}_3 \cdot 4\text{H}_2\text{O}$. F. Schaffgotsch said the precipitate is at first flocculent, but later becomes crystalline. When a mixture of cold aq. soln. of magnesium sulphate or chloride and ammonium sesquichloride is allowed to stand for several hours, A. F. de Fourcroy and C. F. Bucholz observed that crystals of the double salt are formed. G. C. Wittstein also found a soln. of magnesia in an aq. soln. of ammonium sesquicarbonate furnishes a crop of crystals of the double salt in a short time. P. A. Favre observed similar results on shaking magnesia alba with an aq. soln. of ammonium carbonate, and allowing the filtered soln. to crystallize. According to F. Schaffgotsch, soln. of ammonium carbonate, with or without free ammonia, furnish the double salt on being treated with a magnesium compound; and E. Divers added that if a soln. with one mol of magnesium sulphate be treated with less than four mols of ammonium carbonate, magnesium carbonate first precipitates, and the double salt is afterwards deposited: if the soln. contains two mols of ammonium chloride for every mol of magnesium sulphate, no magnesium carbonate is precipitated. If the ammonium carbonate is added slowly, the double salt is formed, and all the magnesium is precipitated as the double salt when four mols of ammonium carbonate have been added; if a larger proportion of ammonium chloride is present, more ammonium carbonate is required for the complete precipitation of the magnesium. R. Weber and F. Schaffgotsch studied the occlusion of salts by the precipitated ammonium magnesium carbonate; they find potassium salts are occluded so tenaciously as not to be removed by washing—sodium salts are not so occluded. According to J. W. Döbereiner, the crystals form translucent rhombohedrons. N. J. B. G. Guibourt observed that the damp crystals give off ammonia when exposed to air, but not if the crystals have been well dried over calcium chloride. E. Divers found that the dry distillation of the double salt gives a liquid which deposits crystals of ammonium sesquicarbonate, $(\text{NH}_4)_4\text{H}_2(\text{CO}_3)_3 \cdot \text{H}_2\text{O}$, and a sublimate of the same salt. The ignition of the salt yields magnesium oxide. According to C. F. Bucholz, the crystals are decomposed by water; and P. A. Favre, N. J. B. G. Guibourt, and E. Divers found that with cold water, magnesium carbonate is formed, and with hot water, magnesia alba. According to E. Divers, the double salt is sparingly soluble in an aq. soln. of ammonium carbonate, and very soluble in an aq. soln. of ammonium chloride. If a magnesium salt be treated with a large excess of ammonium hydrocarbonate, H. St. C. Deville obtained

tetrahydrated **magnesium ammonium hydrocarbonate**, $\text{Mg}(\text{NH}_4\text{CO}_3)(\text{HCO}_3) \cdot 4\text{H}_2\text{O}$, as a crystalline powder which forms normal ammonium magnesium carbonate by the loss of ammonia and water. A higher hydrate, $\text{Mg}(\text{NH}_4\text{CO}_3)(\text{HCO}_3) \cdot 5\frac{1}{2}\text{H}_2\text{O}$, is produced by working at a low temp. R. Engel could not make this salt, but G. von Knorre succeeded in doing so.

The term *dolomite* is employed somewhat loosely for limestones containing notable quantities of magnesium carbonate; and it is also employed in a more specific sense for the double **calcium magnesium carbonate**, $\text{CaMg}(\text{CO}_3)_2$, which occurs as a crystallized mineral and as a massive rock, and in which the ratio $\text{CaO} : \text{MgO}$ is as 1 : 1. H. B. Saussure³ first named the mineral *dolomie* after D. Dolomieu, who observed many of the peculiar properties of what he called *pierres calcaires très-peu effervescentes avec les acides*; R. Kirwan called it *dolomite*. Normal dolomite has also been called *dolomite spar*, *bitter spar*, or *bitter salt spar*. In some cases part of the magnesium has been replaced by iron to furnish *ferruginous dolomites*, which, when coloured brown, are called *brown spar*, and, when coloured a pale brown, *pearl spar*; while varieties approximating to $2\text{CaCO}_3 \cdot \text{MgCO}_3 \cdot \text{FeCO}_3$ are called *ankerite*, after M. Anker of Styria. Varieties of dolomite of minor importance have been named after particular localities—e.g. *miemite* from Miemo (Tuscany), *tharandite* from Tharand (Dresden), and *guruhofite* from Gurhof (Austria). The latter was analyzed by A. Baumgarten and J. R. von Holger in 1837, and was shown by H. von Foullon to be most probably a mixture. L. Blum found what he regarded as $2\text{MgCO}_3 \cdot \text{CaCO}_3$ in an iron mine in Lothringen, and he regarded it as a new mineral species, *lessbergite*; but W. Bruhns showed that lessbergite is probably a mixture. Several more or less ephemeral names have been used for varieties of dolomite—*conite*, *brossite*, *tautocline*, etc. What appears to have been a kind of ankerite was analyzed by P. Woulfe in 1779. Similarly also manganese carbonate may replace magnesium carbonate, furnishing *manganiferous dolomites*—a specimen from Kuttenberg (Bohemia) was named *kutnohorite* by A. Bukowsky. A *nickeliferous dolomite* from Taraps (Switzerland) has been called *taraspite* by C. von John; a *cobaltiferous dolomite* was reported by W. Gibbs from Przibram; and a *zinciferous dolomite* by K. Monheim from Altenberg. There are also *dolomitic marbles*. The magnesian limestones are presumably mixtures of dolomite and calcite, although brucite is sometimes present—e.g. *predazzite* and *pencatite* are mixtures of calcite and brucite.

Dolomite, like limestone, is found in large beds covering whole tracts of country and mountain ranges, as in the North of England, Tyrol, and many other places. Numerous analyses have been made of normal dolomites and dolomites with a low proportion of iron;⁴ of ferruginous dolomites, including ankerite and brown spar;⁵ and of manganiferous dolomites.⁶

The formation of dolomite in nature.—In the formation of marine dolomites in nature, (i) the mixed carbonates may be directly precipitated in shallow waters, by changes of temp., of conc. of atm. carbon dioxide, or by ammonium carbonate derived from the decomposition of marine organisms. This hypothesis has been advocated by G. Leube,⁷ C. W. Gümbel, T. Scheerer, T. S. Hunt, etc. (ii) The limestone formed by the accumulation of the shells or skeletons of marine organisms is magnesian. This statement is emphasized by A. G. Högbom's analyses of oceanic oozes; and by F. W. Clarke and W. C. Wheeler's analyses of the inorganic parts of marine organisms, etc. The more soluble calcium carbonate may be leached away by percolating waters until the dolomitic ratio is approximated. H. Grandjean, A. G. Högbom, J. D. Dana, and others have produced evidence of this action. The borings on the atoll of Funafuti, examined by J. W. Judd, showed a marked enrichment in magnesium carbonate near the surface, owing presumably to the leaching out of the lime salts. The coralline rock may also be enriched by the magnesium salts contained in sea-water. The precipitation of magnesium carbonate from its soln. in sea-water by calcium carbonate has been established by the experiments of T. Scheerer and F. Hoppe-Seyler. T. Scheerer noted that powdered chalk

precipitates magnesium carbonate from a soln. of the hydrocarbonate, and carbonated waters can dissolve calcium carbonate out of magnesian limestones.

The synthesis of dolomite.—J. C. G. de Marignac obtained dolomite artificially by heating calcium carbonate with a soln. of magnesium chloride to 200° under 15 atm. press. After 2 hrs.' heating a little of the calcium carbonate was dolomitized, but after 6 hrs.' heating, the product was richer in magnesite than is dolomite itself. A. von Morlot heated powdered calcite with a soln. of magnesium sulphate in a sealed tube at 200° and found that a mixture of dolomite and gypsum was formed; W. Haidinger pointed out that these two minerals are in frequent association. This reaction appears to be reversible because H. C. Sorby obtained efflorescences of magnesium sulphate in Permian limestones, and they are not uncommon in gypsum quarries. J. Durocher heated fragments of porous limestone with dry magnesium chloride to dull redness in a closed gun-barrel so that the vapour of the chloride impregnated the carbonate. The limestone was partially changed to dolomite. H. St. C. Deville saturated chalk or corals with a soln. of magnesium chloride, and heated the mixture on a sand-bath. The lime was partially replaced by the magnesia. K. Spangenberg heated vaterite with a soln. of sodium carbonate and magnesium chloride at 180° – 200° in an autoclave under a press. of 50 atm. of carbon dioxide, and obtained dolomite. G. Linck effected the synthesis of dolomite by adding calcium chloride to a mixture of soln. of magnesium chloride, magnesium sulphate, and ammonium sesquicarbonate, when the amorphous precipitate becomes crystalline, with the composition and optical properties of dolomite, when gently heated in a sealed tube. W. Meigen failed to verify G. Linck's result. L. Bourgeois and H. Traube obtained dolomite by heating a mixture of magnesium and calcium chlorides with potassium cyanate in a sealed tube at 130° . F. W. Pfaff found that the products of organic decay—ammonium carbonate and sulphide, hydrogen sulphide, etc.—probably assist in the dolomitic process; he found that when a current of carbon dioxide is passed for a long time through a warm soln. of the sulphates and chlorides of magnesium and calcium, the slow evaporation of the soln. at 20° – 25° , yields a residue containing a double carbonate insoluble in dil. hydrochloric acid. It is suggested that these conditions might be approximately paralleled in the case of sea-water and thus dolomite might be formed.

C. J. B. Karsten found magnesium carbonate dissolves slowly in a conc. soln. of calcium chloride, and the freshly precipitated carbonate was found by T. S. Hunt to dissolve copiously in that menstruum. According to C. A. Gössmann, the soln. decomposes when boiled, forming a precipitate of calcium carbonate and magnesium chloride. The spontaneous evaporation of a soln. of calcium and magnesium carbonates in carbonated water mixed with calcium chloride was found by A. Bineau to give a precipitate of calcium carbonate, and if evaporated by the aid of heat, a precipitate of calcium carbonate mixed with a little magnesium carbonate. G. Bauck boiled a soln. of equal parts of magnesium and calcium carbonates in carbonated water along with some calcium and magnesium chlorides, and found the precipitate contained a larger proportion of calcium than magnesium the more prolonged the boiling. With slow heating very little, and with rapid heating a lot, of magnesium salt is precipitated; when the alkaline liquid is allowed to stand some days, the magnesium precipitate is redissolved. According to T. S. Hunt, sodium hydrocarbonate precipitates at first almost wholly calcium carbonate from a mixed soln. of calcium and magnesium chlorides; and then follows hydrated magnesium carbonate. T. S. Hunt precipitated mixtures of calcium and magnesium carbonates from hydrocarbonate soln. by alkali carbonates; when the pasty mass formed by precipitation was heated to a temp. exceeding 120° , combination occurred, and dolomite was formed. T. Scheerer obtained mixtures but no dolomite when a soln. of calcium and magnesium hydrocarbonates is evaporated spontaneously at ordinary temp. Temp. is evidently an important factor in the formation of dolomite. F. Hoppe-Seyler obtained no dolomite by allowing a soln. of magnesium chloride to act on calcium carbonate for many months; nor by allowing sea-water,

sat. with carbon dioxide, to stand in contact with an excess of calcium carbonate, for four months in a closed flask; but when magnesium salts or sea-water were heated with calcium carbonate in sealed tubes, dolomite and magnesite were formed. Calcium carbonate heated to over 100° with a soln. of magnesium hydrocarbonate gave a similar result.

C. Klement tried aragonite, the less stable form of calcium carbonate, in place of calcite, and he found that a conc. soln. of magnesium sulphate at 60° will partially transform coral or aragonite into magnesium carbonate under conditions where calcite is but slightly attacked; a mixed soln. of magnesium sulphate and sodium chloride at 90° attacked aragonite rapidly, forming a product with 41.5 per cent. of magnesium carbonate. Magnesium chloride was not so active as the sulphate. Although the product of these reactions is not dolomite, but rather a mixture of the carbonates, he believed that in time mixtures of this kind would combine and crystallize into dolomite. He attributed the formation of dolomite to the action of sea-water in closed lagoons on the aragonite of coral rock. Pseudomorphs of dolomite after calcite have been reported by R. Blum, and others.

The deposition of crystalline dolomite, and of magnesian travertine, from natural waters has been observed, as well as, what might be called, the accidental formation of dolomite crystals. Thus, J. Girardin noted that the travertine deposited by the mineral spring of St. Allyre (Clermont) is rich in magnesium carbonate, but whether present as dolomite has not been ascertained. A. Moitessier found that crystals of dolomite were deposited inside a badly closed bottle containing mineral water; and A. Terreil found similar crystals were formed in a sealed tube containing water from a hot spring near the Dead Sea. Hence, L. Lartet concluded that the dolomites in the region of the Dead Sea were probably formed by the impregnation of limestones by magnesian waters. E. von Gorup-Besanez also found spring water from the dolomites of the Jura, containing calcium and magnesium carbonates in the dolomitic (1 : 1) ratio, to deposit the mixed salts and not the double compound. Although in the laboratory, a moderately high temp. is needed for the combination of the mixed carbonates to form the double salt, it may be that union between the moist particles does actually take place very slowly in the cold and possibly under a moderate press.

The properties of dolomite.—The crystals of dolomite are shown by P. Groth⁸ to belong to the trigonal system and to have the axial ratio $a : c = 1 : 0.8322$, and $\alpha = 102^{\circ} 53'$. H. Baumhauer, P. Koller, etc., have studied the corrosion figures. G. Tschermak has pointed out that the corrosion figures show that dolomite is not hemihedral like calcite, but rather tetartohedral; and this is in agreement with F. Becke's observations on the twinning of dolomite crystals. In order to explain the magnesia in calcites, P. Groth assumed an isomorphism between calcite and dolomite, and he regarded the latter as a true double salt; but F. Becke, *au contraire*, showed that while the crystals of calcite and magnesite belong to the scalenohedral class, dolomite crystallizes in the rhombohedral class. The **X-radiograms** of dolomite have been studied by H. Haga and F. M. Jäger, F. Rinne, and A. Johnsen.

The **specific gravity** of dolomite has been determined on most of the samples which have been analyzed—*vide supra*—and the results range from 2.75 to 3.10. Most of these samples were not of a high degree of purity. F. E. Neumann's value⁹ is 2.916; F. Ott's, 2.89; G. Tschermak's, 2.924; E. Madelung and R. Fuchs' 2.8735 (0°); and F. Senft's 2.85. The best representative value for dolomite is taken by J. W. Retgers to be 2.872; for calcite, 2.712; and for magnesite, 3.017. The mean sp. gr. calculated on the assumption that dolomite is a mechanical mixture is 2.843, a difference of 0.029. The contraction which occurs in the formation of dolomite is therefore taken by J. W. Retgers to indicate that dolomite is a chemical individual, a true double salt. This double salt does not form isomorphous mixtures with either calcite or magnesite, but stands isolated in its physical properties outside the series of mixtures. The primitive forms of calcite and magnesite are two rhombohedra with slightly different angles; and these angles vary with the temp.

and elastic actions. Calcium carbonate, however, can form a very small range of mixed crystals with a little magnesium carbonate, and these crystals are isomorphous with those of calcite, so that the magnesite here occurs as a labile dimorphous modification which does not belong to the same class as calcite. Similarly also with respect to the admixture of a little calcite with magnesite, the calcite is present as a labile modification isomorphous with magnesite. To summarize, it is probable, though not yet established, that dolomite is a double salt; but there is yet no further evidence of the assumed isodimorphism of calcite and magnesite, *via* two unknown labile phases. The **hardness** of dolomite on Mohs' scale is 3.5 to 4.0. W. Voigt found the **elastic modulus** to be 14,600 kgrms. per sq. mm. in the direction of the principal axis; 8330 kgrms. per sq. mm. in a direction perpendicular to that axis; 14,400 and 18,700 kgrms. per sq. mm. respectively in directions inclined at angles -21.5° and $+21.5^\circ$ to the principal axis. E. Madelung and R. Fuchs gave 1.21×10^{-6} megabars per sq. cm. for the **compressibility** of dolomite.

According to F. Findeisen¹⁰ when dolomite is heated, the magnesium carbonate first decomposes, and then the calcium carbonate. G. A. Bole and J. B. Shaw obtained similar results. K. Friedrich and L. G. Smith found that different specimens of dolomite began to decompose at from 730° to 745° , and the heating curves showed a maximum thermal change at about 750° or 760° . According to J. A. Hedvall and J. Heuberger, if the oxides of the alkaline earths and magnesium be arranged in order of increasing basicity, MgO, CaO, SrO, BaO, then the oxide of the more basic metal will on heating with the carbonate of the less basic element be changed into the carbonate without the evolution of gas and at a temp. well below the temp. of dissociation of the carbonate taken. The temp. of the reaction decreases and the heat effect increases with increasing difference of basicity, for example, $\text{MgCO}_3 + \text{BaO} = \text{BaCO}_3 + \text{MgO} + 19$ cal. at 230° ; $\text{SrCO}_3 + \text{BaO} = \text{BaCO}_3 + \text{SrO} + 6.14$ cal. at 280° . According to H. St. C. Deville, and A. Hauenschild, dolomite which has been heated to 360° – 400° and made into a paste with water, hardens under water like a cement; but if pre-heated to redness, it disintegrates when placed in water.

The thermal properties of dolomite have not been closely examined, but the same remark applies to the physical properties generally. It is remarkable, said H. Leitmeier, that so little is known about the physical properties of a substance on which so much work, relating to its genesis and constitution, has been expended. H. Fizeau measured the **coefficient of linear expansion**, and found $\alpha = 0.00001968$ in a direction parallel to the chief axis, and 0.00000367 when vertical to the chief axis. H. Kopp found the coeff. of cubical expansion to be 0.000035 per degree between 13° and 43° . H. Kopp found the **specific heat** to be 0.206 between 18° and 47° ; H. V. Regnault, 0.21743 between 26° and 99° ; and R. Ulrich and E. Wollny, 0.2218 between 18° and 98° .

According to H. Fizeau, the **double refraction** is strongly negative $\omega - \epsilon = 0.189$; and the **index of refraction** for Na-light is $\omega = 1.68174$ for the ordinary ray, and $\epsilon = 1.50256$ for the extraordinary ray. K. Eisenhut¹¹ measured the refractive indices of eight specimens of dolomite with gradually increasing proportions of iron, and found that the index of refraction increases. W. Schmidt found the **dielectric constant** of a crystal of dolomite in a direction parallel to the chief axis to be 6.70 , and normal to that axis 7.77 . W. Voigt studied the **magnetic properties** of crystals of dolomite.

The solubility of dolomite.—According to A. Cossa,¹² a litre of distilled water sat. at 18° and 750 mm. press. with carbon dioxide, dissolves 0.320 grm. of dolomite, 0.15 grm. of magnesite, and 1.0 to 1.2 grms. of calcite. H. Leitmeier found that at ordinary temp. a litre of water sat. with carbon dioxide dissolves 0.11 grm. of dolomite. C. G. C. Bischof found that if the dolomite contains a little magnesite or calcite, these are first dissolved. T. Scheerer found that the calcium carbonate was dissolved much faster than magnesium carbonate. C. Doelter and R. Hoernes, and E. von Gorup-Besanez did not find much difference, though the calcium

carbonate dissolved a little more quickly. When the soln. is evaporated, the dissolved carbonates do not reform dolomite, although F. Hoppe-Seyler showed that at temp. near 200° , dolomite can be recrystallized from carbonated water.

The early reports on the action of acids on dolomite and magnesian limestones appear contradictory; possibly some cases can be explained by the presence of forms of magnesium carbonate which dissolve, in acids—some slowly, some quickly. In 1791, D. Dolomieu stated that cold dil. *mineral acids* do not act very well on dolomite. C. J. B. Karsten treated a magnesian limestone with cold dil. acetic acid and obtained an undissolved residue of dolomite; in another limestone, he obtained a residue of magnesium carbonate *ohne Spur von Kalk*; and therefore inferred that the former was a mixture of calcite and dolomite, the latter a mixture of calcite and magnesite. A. Damour similarly treated a limestone from Mt. Somma and found that it all dissolved even though the proportions of calcium and magnesium carbonates were as 4 : 1. C. Schmidt also obtained a similar result with a Russian limestone. P. Forchhammer found that dil. *acetic acid* removed the excess of calcite from a dolomitic limestone, but scarcely affected the dolomite. C. Doelter and R. Hoernes, A. Vesterberg, and F. Hoppe-Seyler obtained a similar result. On the other hand, F. W. Pfaff, J. Roth, and T. S. Hunt found a considerable proportion of magnesium salt was dissolved. K. Haushofer made an extensive study of the solubility of dolomite in acetic acid, and found that the duration of the treatment, the conc. of the acid, and the temp. are of great importance. The effect of temp. and the time of treatment are usually greater with dil. than with conc. acetic acid. With normal dolomites, the magnesia dissolves more readily than the lime, while with dolomites containing an excess of calcite, the calcium salt dissolves faster than the magnesium salt. Citric acid acts more energetically than acetic acid. T. Liebe found that a dolomitic limestone was enriched by treatment with cold dil. *hydrochloric acid* owing to the preferential dissolution of the calcium carbonate, and C. E. Schafhäütl made a similar observation with *nicht allzu* conc. hydrochloric acid. For the action of *carbonic acid*, that is, carbonated water, or a soln. of carbon dioxide in water, see the decalcification of dolomite. A. Vesterberg found that magnesium carbonate in some cases dissolves as fast as the calcium carbonate; and that the presence of magnesium chloride depresses the speed of dissolution of magnesium carbonate in carbonated water.

According to H. Reinsch, dolomite is not decomposed by boiling it with calcium sulphate and water, but if calcined dolomite is treated with carbon dioxide and again exposed to the action of calcium sulphate and water, F. Findeisen found that magnesium sulphate is formed. According to C. J. B. Karsten, dolomite behaves like magnesite towards an aq. soln. of *sodium chloride*, and it is not decomposed by an aq. soln. of *calcium chloride*. P. Berthier fused a mixture of four mols of *sodium carbonate* with one of dolomite, and on cooling obtained a clear mass with a crystalline fracture. If a very high temp. be employed carbon dioxide is evolved, and with a smaller proportion of sodium carbonate, the evolution of gas occurs as soon as the mixture begins to soften.

The so-called *hydrolomite* or *hydromagnocalcite* found in stalagmitic and concretionary forms at Mt. Somma, Vesuvius, is a calcium magnesium carbonate with 6 to 17 per cent. water of hydration. R. Hermann¹³ called a similar mineral *pennite*. C. U. Shepard found a variety which he called *hydronickel magnesite* tinted with nickel in Texas, Pa. A variety called *hydromanganocalcite* contains manganese. According to C. F. Rammelsberg, and F. von Kobell, hydrolomite is really a mixture of hydromagnesite and dolomite. T. S. Hunt obtained what he regarded as a hydrated calcium magnesium carbonate, $\text{CaCO}_3 \cdot \text{MgCO}_3 \cdot 5\text{H}_2\text{O}$, by the action of a small excess of sodium carbonate on a soln. containing equi-mol. proportions of magnesium and calcium chlorides. If this precipitate is kept in contact with sea-water for some days, it forms small transparent prismatic crystals; and by using insufficient sodium carbonate for complete precipitation, he obtained prismatic crystals of what he regarded as $7\text{MgCO}_3 \cdot 10\text{CaCO}_3 \cdot 21\text{H}_2\text{O}$.

It is difficult to *distinguish calcite from dolomite*. J. Lemberg¹⁴ tried ferric chloride, and silver nitrate soln. The latter stains the two minerals unequally after ignition; and E. Hinden has stated that limestone is coloured reddish-brown by a soln. of ferric chloride,

and blue by a soln. of cupric sulphate, while dolomite is not affected—O. Mahler got poor results with ferric chloride, but good ones with the cupric sulphate. According to J. Lemberg, a soln. of aluminium chloride and hæmatoxylin or extract of logwood—*Lemberg's solution*—deposits a violet coating on calcite surfaces, but leaves dolomite uncoloured. F. Cornu has pointed out that if the powdered minerals are covered with water with a few drops of phenolphthalein, calcite gives an intense coloration while dolomite is not affected.

G. Bollmann allowed a soln. of calcium chloride or nitrate to act for 1–8 hrs. on hydrated magnesium carbonate at 120°–200°, but did not get any sign of the formation of dolomite, and he assumed that the reaction requires a long time; on the other hand, he found that the formation of trihydrated **distrontium magnesium carbonate**, $2\text{SrCO}_3 \cdot \text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, proceeds more quickly when carbon dioxide is passed into a sat. soln. of strontium nitrate with magnesium carbonate in suspension, for 2 hrs. at 150°–170°. When the action is allowed to continue for a longer time, the product approximates to a *strontia-dolomite*, $\text{SrCO}_3 \cdot \text{MgCO}_3$. When a soln. of barium nitrate is treated in a similar manner, **barium magnesium carbonate**, $\text{BaCO}_3 \cdot \text{MgCO}_3$, is formed.

W. F. Foshag¹⁵ groups the following minerals of the general formula $\text{MgCO}_3 \cdot 5\text{Mg}(\text{OH})_2 \cdot 2\text{R}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$, as **hydrotalcites**. C. Hochstetter, R. Hermann, C. U. Shepard, C. F. Rammeisberg, and W. R. Johnson described the mineral *hydrotalcite*, $\text{MgCO}_3 \cdot 5\text{Mg}(\text{OH})_2 \cdot 2\text{Al}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$. C. U. Shepard called it *houghite*, and R. Hermann, *völkernite*; W. F. Petterd, L. K. Ward, L. Hezner, and A. Himmelbauer described *stichtite*, $\text{MgCO}_3 \cdot 5\text{Mg}(\text{OH})_2 \cdot 2\text{Cr}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$; L. J. Igelström, H. Sjögren, R. Mauzelius, and G. Flink, *pyroaurite*, $\text{MgCO}_3 \cdot 5\text{Mg}(\text{OH})_2 \cdot 2\text{Fe}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$; and E. Artini, and A. Pelloux, *brugnattelite*, $\text{MgCO}_3 \cdot 5\text{Mg}(\text{OH})_2 \cdot \text{Fe}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$ —but whose composition has not yet been definitely established. A comparison of the properties of these minerals is indicated in Table VIII.

TABLE VIII.—COMPARISON OF THE PROPERTIES OF THE HYDROTALCITES.

Hydrotalcite.	Pyroaurite.	Stichtite.	Brugnattelite.
White	Light brown	Lavender purple	Rose, light brown
Translucent	Translucent	Translucent	Translucent
Uniaxial	Uniaxial	Uniaxial	Uniaxial
Cleavage basal	Cleavage basal	Cleavage basal	Cleavage basal
Sp. gr. 2.04–2.09	Sp. gr. 2.07	Sp. gr. 2.12	Sp. gr.
n. 1.510	n. 1.55 (approx.)	n. 1.542	n. 1.533
Biref. weak	Biref. weak	Biref. 0.026	—
Pleochroism, none	Pleochroism, none	Very slightly pleochroic	Pleochroic

§ 19. Magnesium Nitrates

The so-called *nitromagnesite* is said to occur as an efflorescent mass of hexahydrated magnesium nitrate besides the so-called nitrocalcite. A soln. of **magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2$, is obtained by the action of nitric acid on magnesium carbonate, hydroxide, or oxide. As T. Graham¹ showed, when this soln. is evaporated on a water-bath, and cooled to ordinary temp. crystals of **hexahydrated magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, are formed; but if the soln. be cooled below -20° , crystals of **enneahydrated magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$, appear. R. Funk found the transition point for the ennea- and hexa-hydrates to be -18° . The relation between these hydrates appears from the solubility curves. The following results by R. Funk refer to the **solubility** of the hexahydrated salt in grams per 100 grms. of sat. soln:

	-4.5°	0°	18°	40°	80°	90°	89°	77.5°	67°
$\text{Mg}(\text{NO}_3)_2$. . .	39.50	39.96	42.33	45.87	53.69	57.81	63.14	65.67	66.55

where 90° , according to J. M. Ordway, represents the m.p. of the hexahydrate, and the succeeding numbers give a reversed curve. This means that soln. can be prepared with less water than is contained in the hexahydrate which occurs as the solid phase; and they can be regarded as soln. of the hexahydrate in the anhydrous salt. The numbers for the enneahydrate are likewise

	-7.8°	-20°	c. -29°	-23°	-20°	18°
$\text{Mg}(\text{NO}_3)_2$. . .	15.00	27.4	34.6	35.44	36.19	38.03

where -18° is the transition point for the ennea- and hexa-hydrates, and the first two pairs in the series refer to the ice-line with the eutectic at *circa* -29° , according to F. Rüdorff. According to A. Ditte, if an aq. soln. of magnesium nitrate be heated carefully until a few gas bubbles begin to develop, the remaining colourless liquid is in a state of supersaturation at ordinary temp., and on shaking heat is developed, and crystals of **trihydrated magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, are deposited. According to H. Lescœur, the same hydrate is formed from a sat. soln. of the nitrates mixed with an equal vol. of nitric acid; and he found that when the hexahydrate is heated to 65° , the vap. press. suddenly falls from 80 mm. to 25 mm., corresponding with the formation of the trihydrate. A. Ditte also claimed to have prepared short prismatic crystals of **dihydrated magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, by heating the trihydrate a little above the m.p., but not sufficiently high for the evolution of red vapours; and dissolving the residue in monohydrated nitric acid which dissolves 5 per cent. of the salt at 2° , and 11 per cent. at 80° . The hot sat. soln. furnishes crystals of the dihydrate. A. Chodneff prepared this hydrate as a white hygroscopic powder by allowing the hexahydrate to stand over conc. sulphuric acid. R. Funk was unable to confirm the preparation of the dihydrate. Still further, T. Graham obtained what was regarded as **monohydrated magnesium nitrate**, $\text{Mg}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, by heating the hexahydrate to 100° ; and A. Ditte by heating magnesium nitrate until red fumes began to appear, dissolving the residue in as little hot monohydrated nitric acid as possible. Fine crystals of the monohydrate appear when the soln. is cooled.

According to A. Chodneff, the **crystals** of the hexahydrate belong to the triclinic system, but J. C. G. de Marignac found they are really monoclinic prisms, with axial ratios $a : b : c = 0.5191 : 1 : 0.9698$, and $\beta = 92^\circ 56'$. L. Playfair and J. P. Joule gave 1.464 for the **specific gravity** of hexahydrated magnesium nitrate. F. Mylius and R. Funk found that at 18° a sat. soln. of magnesium nitrate contained 43.08 per cent. $\text{Mg}(\text{NO}_3)_2$, and had a sp. gr. 1.394. A. C. Oudemans gave for the sp. gr. of soln. containing

$\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$. . .	1	5	10	20	30	40	45	49
Sp. gr. at 14° . . .	1.0034	1.0202	1.0418	1.0869	1.1347	1.1909	1.2176	1.2397

Measurements have also been made by H. C. Jones, H. Schiff, by D. Dijken, and by

H. T. Barnes and A. P. Scott. The vol. of a soln. in 100 mols of H_2O at θ° between 0° and 60° was represented by N. S. Tschernay by the equation $v=1+0.0001552\theta+0.000003483\theta^2$. J. Wagner found the **viscosity** of N -, $\frac{1}{2}N$ -, $\frac{1}{4}N$ -, and $\frac{1}{8}N$ -soln. of magnesium nitrate at 25° to be respectively 1.1706, 1.0824, 1.0396, and 1.0198. Measurements were also made by S. Arrhenius, and K. Mützel. A. Strickler and J. H. Mathews studied the electric endosmose of magnesium nitrate.

According to A. Chodneff, the crystals of the hexahydrate lose 28.25 per cent.—nearly two-thirds—of water of crystallization when confined over conc. sulphuric acid; and he stated that the **melting point** of the hexahydrate is 100° ; J. M. Ordway, and W. A. Tilden gave 90° . A. Chodneff found that the hexahydrate loses 34.14 per cent. of water at its m.p. and congeals to a glass-like mass. A. Chodneff found that the percentage loss on calcination:

	110°–115° (6 hrs.)	115°–120° (6 hrs.)	120°–125° (23 hrs.)	140°–150° (28 hrs.)	150°–155° (6 hrs.)	210° (5 hrs.)
Loss	20.87	28.97	31.05	34.72	35.10	35.32

T. Graham was unable to drive off all the water at 400° , and at a dull red heat it loses the remainder of the water, and at the same time gives off nitrogen peroxide and oxygen. D. Gernez found that in air free from carbon dioxide, nitric acid is given off when magnesium nitrate is heated to 150° ; and J. C. G. de Marignac found the crystals to be stable in dry air.

According to A. Ditte, when trihydrated magnesium nitrate is melted and heated to the temp. at which red fumes are evolved, and the product leached with water, **magnesium trioxynitrate**, $3MgO.Mg(NO_3)_2$, remains as white tabular crystals. A. Chodneff heated the hexahydrate with stirring until the mass melted and lost all its water. The product was washed with water, and there remained a white basic nitrate, **magnesium dioxynitrate**, $2MgO.Mg(NO_3)_2$, which is insoluble in alcohol and water, but soluble in acids. There is really nothing to establish the individuality of those, although G. Didier made crystals of **pentahydrated magnesium dioxynitrate** by dissolving 200 grms. of hexahydrated magnesium nitrate in 150 c.c. of water at 100° , and adding 10 grms. of magnesia prepared at a low temp. -350° – 400° . The temp. is gradually raised to 150° and the filtrate, preserved in a closed vessel, deposits a flocculent precipitate in a few days. The precipitate is isolated by suction and press. keeping it as much as possible out of contact with the carbon dioxide of the atm. The microscopic crystals consist of doubly refracting needles which are rapidly decomposed by cold water or absolute alcohol, with the separation of magnesium hydroxide.

J. C. G. de Marignac found for the **specific heat** of a soln. of a mol of $Mg(NO_3)_2$ in n mols of water, between 21° and 52° ,

n	15	25	50	100	210
Sp. ht.	0.6777	0.7568	0.8517	0.9145	0.9537
Mol. ht.	283.7	453	893	1782	3575

H. C. Jones and co-workers measured the lowering of the **freezing point** of aq. soln. of magnesium nitrate and found for soln. with 1.142, 0.921, and 32.07 grms. of $Mg(NO_3)_2$ per 100 grms. of water, the f.p. were respectively -0.370° , -3.559° , and -22.500° , and the mol. lowering of the f.p. respectively 4.8° , 5.75° , and 10.40° .

According to J. Thomsen, the **heat of formation**, $(Mg, O_2, N_2O_4, 6H_2O)=214.53$ Cals.; and, according to M. Berthelot, $Mg(OH)_2+2HNO_{3aq.}=27.6$ Cals. J. Thomsen gave -4.22 Cals. for the **heat of solution** of a mol of the hexahydrate in 400 mols of water, and S. U. Pickering, -4.547 ; the latter found 0.936 Cal. for the heat of soln. in alcohol. D. Dijken found the following difference in the **refractive indices** of the soln. and water for a mol. of $Mg(NO_3)_2$ in v litres of water between 15° and 16.5° :

v	1	4	16	32	64	128
Diff.	0.012258	0.003086	0.0007890	0.0003982	0.0001991	0.0001020

According to C. Chéneveau, the value of $(\mu_D-1)D$ in dil. soln., decreases with the

press. of the solute. W. N. Hartley found that the **absorption spectrum** for a soln. with 256.4 grms. per litre, and thickness 4 mm., gave bands λ^{-1} , 3069 to 3772; and for a thickness 2 mm., absorption bands for λ^{-1} , 3069 to 3772; and for a thickness 2 mm., absorption bands for λ^{-1} , 3149 to 3504. J. R. Collins measured the ultra-red absorption spectrum of aq. soln. of the nitrate. F. Kohlrausch and L. Holborn give for the **equivalent conductivity**, λ , of magnesium nitrate, at 25°; H. C. Jones gives for the mol. conductivity, μ , at 0°, the percentage **ionization** α , and the temp. coeff., k , of soln. of a mol of the salt in v litres of water at 0°:

v	.	.	8	32	64	128	256	512	1024
λ (25°)	.	.	—	104.6	111.0	115.7	119.0	122.9	125.6
μ (0°)	.	.	88.91	101.55	110.78	119.01	120.68	123.34	122.89
α (0°)	.	.	72.1	82.4	89.9	96.5	97.9	100.0	99.7
k (0°–12.5°)	.	.	2.76	3.23	3.58	3.74	3.97	3.99	4.06

C. A. Kraus and J. E. Bishop measured the conductivity of soln. of magnesium nitrate in mixtures of propyl alcohol and water. A. Chassy gave data for the **transport numbers** of the ions.

J. W. Thomas found that **hydrogen chloride** reacts vigorously with heated magnesium nitrate and red fumes of nitrogen peroxide are evolved. T. Graham found the hydrates of magnesium nitrate are all hygroscopic, and readily soluble in **alcohol**, and he found that a hot sat. soln. of anhydrous magnesium nitrate, in alcohol, forms a double compound $\text{Mg}(\text{NO}_3)_2 \cdot 4\frac{1}{2}\text{C}_2\text{H}_5\text{OH}$; and A. Chodneff represented the composition $\text{Mg}(\text{NO}_3)_2 \cdot 3\text{C}_2\text{H}_5\text{OH}$. E. C. Franklin and C. A. Kraus found magnesium nitrate to be soluble in **liquid ammonia**, and the soln. immediately gives a precipitate with ammonium chloride; one is formed more slowly with ammonium bromide, and none at all with ammonium iodide; ammonium sulphide gives a precipitate of $(\text{NH}_4)_2\text{S} \cdot 2\text{MgS} \cdot n\text{NH}_3$; ammonium chromate, and borate also give precipitates with the liquid ammonia soln. of magnesium nitrate. D. N. Jackman and A. Browne studied the ternary systems, $\text{Mg}(\text{NO}_3)_2 - \text{NaNO}_3 - \text{H}_2\text{O}$, and $\text{MgSO}_4 - \text{Mg}(\text{NO}_3)_2 - \text{H}_2\text{O}$, at 25°, and found that no double salts or solid soln. are formed.

§ 20. Magnesium Orthophosphates

Analyses of the guano mineral *bobierrite* or *hautfeullite* from Chile by A. Lacroix,¹ and from Bambe by L. Michel, show that it has a composition corresponding closely to that required for normal **hexahydrated magnesium orthophosphate**, $\text{Mg}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$. According to C. Stein and B. Tollens, it also separates from pathological and from normal urine; small quantities have also been reported in the cereals, in bones, in urinary calculi, and in the intestinal concretions of some animals. T. Graham,² and W. Gregory prepared what has been regarded as hydrated normal magnesium phosphate, $\text{Mg}_3(\text{PO}_4)_2$, by treating a soln. of magnesium sulphate with normal sodium phosphate; the precipitate dried at 100° contains the eq. of $5\text{H}_2\text{O}$. C. Stein and B. Tollens used disodium hydrophosphate, and employed as well conc. soln. made slightly alkaline with sodium hydrocarbonate. A crystalline precipitate forms in 12–24 hrs. K. Kraut recommended mixing magnesium sulphate or chloride with a mixed soln. of disodium hydrophosphate, or of disodium hydrophosphate and borax, the flocculent precipitate soon becomes crystalline. L. Schaffner boiled magnesium hydrophosphate repeatedly with water so long as this acquired an acid reaction, and obtained the normal phosphate; and H. Debray heated the same compound with water in a sealed tube at 120° . G. A. Daubrée prepared rhombic plates of magnesium phosphate by heating magnesium oxide in an atm. of phosphorus pentachloride: $8\text{MgO} + 2\text{PCl}_5 = \text{Mg}_3(\text{PO}_4)_2 + 5\text{MgCl}_2$. A. de Schulten mixed a soln. of 20 grms. of heptahydrated magnesium sulphate in two litres of water and cooled at 10° , with a soln. of 19.4 grms. of dodecahydrated disodium hydrophosphate and 4 grms. of sodium hydrocarbonate in a litre of water, and, after diluting the mixture with a litre of water, allowed it to stand at 20° – 25° for a long time. Crystals of *bobierrite* were slowly formed. He also obtained crystals without using the sodium hydrocarbonate.

Bobierrite occurs in colourless and white needles. A. de Schulten found the artificially prepared **crystals** of the octohydrate, $\text{Mg}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, to be monoclinic prisms, with axial ratios $a : b : c = 0.076 : 1 : 0.74$, and β is about 106° . A. Sachs supposed *bobierrite* to be isomorphous with *vivianite* and *symplesite*. A. Lacroix gave 2.41 for the **specific gravity** of *bobierrite*, and A. de Schulten, 2.195 at 15° , for the artificial product. The latter also found that the synthesized octohydrate did not lose its water of crystallization at 100° , while the hydrated precipitate lost about 82 per cent. of its water at 100° , and still more with a prolonged heating. According to K. Kraut, if precipitated magnesium phosphate be dried over conc. sulphuric acid, the product contains 43.8 per cent. of water; if at 100° , 10.86 per cent.; and if calcined at a red heat 4.77 per cent. of water. L. Schaffner found a very small loss at 100° , a loss of 23 per cent. at 180° , and a further loss of 9.10 per cent. at a red heat, and his analysis of the original phosphate corresponded with $\text{Mg}_3(\text{PO}_4)_2 \cdot 7\text{H}_2\text{O}$; C. Stein and B. Tollens' and H. Debray's analyses of the crystals corresponded with $\text{Mg}_3(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$; C. Stein and B. Tollens, and K. Kraut's analyses of the air-dried precipitate, with $\text{Mg}_3(\text{PO}_4)_2 \cdot 22\text{H}_2\text{O}$; and A. de Schulten's analysis of artificial *bobierrite*, with $\text{Mg}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$. Both T. Graham, and W. Gregory found that the phosphate has a **melting point** near a white heat, and the resulting clear glass is easily soluble in acids. According to M. Berthelot, the **heat of formation** of colloidal normal magnesium phosphate from its elements is 910–6 Cals.; and from magnesium sulphate and normal sodium phosphate is compounded of two factors—the initial formation of an amorphous precipitate, 4.86 Cals., followed by its transformation into crystals which in 5–6 mins. liberate 8.12 Cals. With magnesium chloride, the numbers are respectively –4.44 Cals. and 12.18 Cals. The **heat of neutralization** is $\text{Mg}(\text{OH})_2 + \text{H}_3\text{PO}_4 \text{aq.} = \text{Mg}_3(\text{PO}_4)_2 \text{aq.} + 57.80 \text{ Cals.}$ for the amorphous, and 83.00 Cals. for the crystalline precipitate. *Bobierrite* has a positive **double refraction**.

According to F. K. Cameron and J. M. Bell, the behaviour of the magnesium phosphates in contact with **water** is quite similar to that of the calcium phosphates.

A. Lacroix found bobierite to be insoluble in water, while J. A. Völcker stated that a litre of water dissolves in 7 days 0.205 gm. of the freshly precipitated normal phosphate, and 0.100 gm. of the calcined. J. von Liebig found a litre of water containing 2 grms. of **sodium chloride** dissolves 75.8 mgrms. of the precipitated phosphate; and a litre of water with 3 grms. of sodium nitrate dissolves 61.9 mgrms. According to A. Lacroix, bobierite is soluble in **nitric acid**, and, according to L. Schaffner, normal magnesium phosphate is easily soluble in **acetic acid**. According to B. W. Gerland, when normal magnesium phosphate is suspended in water, it rapidly absorbs **sulphur dioxide**, and forms an oily liquid; if an excess of the phosphate is present it does not alter its composition. A soln. containing a mol of $\text{Mg}_3(\text{PO}_4)_2$ and 4.3 mols of sulphur dioxide furnishes crystals of trihydrated magnesium hydrophosphate when allowed to stand in vacuo, and a similar product, but less hydrated, is gradually deposited in needle-like crystals on adding sodium carbonate; or on boiling the soln. According to L. Grandeau, a double alkali magnesium phosphate is produced when the phosphate is fused with an **alkali sulphate**, but no magnesium oxide is formed. E. Erlenmeyer has shown that an acid **ammonium citrate** soln. dissolves normal magnesium phosphate quite readily, but not so readily in a neutral citrate soln. A. Chizynsky studied the distribution of phosphoric acid between magnesium and **calcium salts**.

According to L. B. G. de Morveau, magnesium oxide forms a white vitrifiable substance when ignited with two parts of sodium ammonium phosphate. J. J. Berzelius also noted the solubility of magnesia in fused sodium ammonium phosphate before the blowpipe. H. Rose also made a **sodium magnesium phosphate**, NaMgPO_4 , by fusing equimolar parts of magnesium pyrophosphate with sodium carbonate; the analysis corresponded with $3\text{MgO} \cdot 3\text{Na}_2\text{O} \cdot 2\text{P}_2\text{O}_5$. L. Ouvrard obtained a substance with the same composition by fusing normal sodium phosphate with magnesium oxide, and extracting the slowly cooled mass with water. The dendritic crystals have a sp. gr. 2.5 at 20° , and they are doubly refracting. H. Rose made anhydrous **potassium magnesium phosphate**, KMgPO_4 , by calcining a mixture of magnesium pyrophosphate and potassium carbonate. R. Weber's analyses of a similar product were found by H. Rose to be too low in alkali for KMgPO_4 , but H. Rose pointed out that R. Weber washed the material with ammoniacal water which by hydrolytic decomposition removed the alkali and left magnesium hydrophosphate behind. L. Grandeau obtained the same compound by heating for many hours at 800° an intimate mixture of magnesium pyrophosphate with 25 times its weight of potassium sulphate, and extracting the cold mass with hot water. A white powder consisting of needle-like crystals remained. According to L. Ouvrard, potassium pyrophosphate or orthophosphate yields rhombic prisms of the salt P_2O_5 , 2MgO , K_2O , previously described by L. Grandeau. Magnesium phosphate yields the same products as the oxide, but the chloride yields a chlorophosphate unless the alkaline phosphate is present in considerable excess. L. Ouvrard's potassium magnesium phosphate had a sp. gr. 2.6 at 20° , and was easily soluble in acids. H. Erdmann and P. Köthner prepared **hexahydrated rubidium magnesium phosphate**, $\text{RbMgPO}_4 \cdot 6\text{H}_2\text{O}$, by mixing soln. of magnesium sulphate and of rubidium phosphate. The crystalline precipitate is not decomposed by boiling water, and it is soluble in cold dil. hydrochloric acid.

M. Berthelot, and A. Quartaroli studied the equilibrium conditions between phosphoric acid, magnesium oxide, and the alkali hydroxides. The latter found that the behaviour of the magnesium oxide is different from that of barium or calcium oxides. Thus, on adding one eq. of magnesia and two eq. of sodium hydroxide to one mol of phosphoric acid, only magnesium oxide is precipitated, whilst if the sodium hydroxide is replaced by potassium hydroxide, a portion of the latter passes into the insoluble state. On adding one eq. of sodium or potassium hydroxide to monomagnesium phosphate, the amount of phosphoric acid precipitated is much less than in the other cases and only amounts to about one-sixth of the total quantity; seeing that dimagnesium phosphate, like the dicalcium salt,

is only very slightly soluble and that the alkali hydroxide present is sufficient to precipitate it, it is probable that soluble double phosphates are formed. M. Schröcker and M. Violet prepared **enneahydrated sodium magnesium phosphate**, $\text{NaMgPO}_4 \cdot 9\text{H}_2\text{O}$, by heating a soln. of equimolar parts of phosphoric acid and sodium carbonate until carbon dioxide is expelled, and to the cold soln., adding magnesia, which has been heated to the lowest possible temp., until the liquid has a neutral reaction. After the mixture has stood some days, microscopic prisms are formed which are freed from the mother liquid by press. The crystals belong to the triclinic system, and, according to K. Haushofer, they have the axial ratios $a:b:c=1.2588:1:1.4380$, and $\alpha=89^\circ 42'$, $\beta=93^\circ 13'$, $\gamma=89^\circ 31'$. M. Schröcker and M. Violet prepared **hexahydrated potassium magnesium phosphate**, $\text{KMgPO}_4 \cdot 6\text{H}_2\text{O}$, in a similar manner; K. Haushofer found the crystals belong to the rhombic system and have the axial ratios $a:b:c=0.5584:1:0.9001$. The crystals lose five-sixths of their water at 100° , and they are decomposed by water. A. Metz obtained crystals of this double salt by adding potassium carbonate to beer.

K. Haushofer prepared an acid double phosphate which he regarded as decapentahydrated *potassium dimagnesium hydrodiphosphate*, but did not describe the method; he said that the crystals were triclinic plates with axial ratios and angles $a:b:c=0.9418:1:0.5003$, and $\alpha=90^\circ 7'$, $\beta=92^\circ 4'$, and $\gamma=95^\circ 48'$. L. Chevron and A. Droixhe prepared crystals of what they regarded as acid phosphates: $\text{K}_2\text{O} \cdot 4\text{MgO} \cdot 2\text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, and $\text{K}_2\text{H} \cdot \text{Mg}_2(\text{PO}_4)_3 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, from mixtures of soln. of potassium dihydrophosphate, potassium hydrocarbonate, and magnesium sulphate of different conc.; but there is no evidence of the chemical individuality of the products.

Crystals of **hexahydrated ammonium magnesium phosphate**, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O}$, were found by G. L. Ulex³ in some old soil, under quantities of cattle dung, in the neighbourhood of Hamburg, and the mineral was called *struvite*, after a Russian statesman; and E. F. Teschemacher called it *guanite*. F. de la Provostaye found the mineral in guano from Patagonia, and it has been reported in guano from other localities. E. P. Pittman, R. W. E. MacIvor and G. vom Rath reported it in the bat guano from the Skipton Caves (Victoria); H. Ludwig found it in intestinal concretions; and it is deposited from decomposing urine. O. B. Bögge found crystals of struvite in extracts from fossil plants; peat extracts, etc.

A. F. de Fourcroy first made the salt by treating magnesium phosphate with ammonium hydrophosphate; J. J. Berzelius mixed a neutral magnesium salt with ammonium hydrophosphate. In both these cases, G. F. Wach found the soln. becomes acidic. L. Blum also preferred sodium phosphate as precipitating agent because the precipitate settles more quickly; while C. Mohr, and W. Gibbs preferred sodium ammonium phosphate because it precipitates more rapidly and completely. A. Riffault mixed a magnesium salt first with ammonium carbonate, and then with disodium hydrophosphate. According to C. A. Lesueur, magnesium hydroxide or carbonate is transformed into ammonium magnesium phosphate when it is allowed to stand in contact with a soln. of ammonium hydrophosphate; and likewise also when magnesium hydrophosphate is treated with aq. ammonia, ammonium sulphide, or ammonium carbonate; C. Stein, and B. Tollens observed a similar result with normal magnesium phosphate. J. W. C. Davis also prepared this salt. A. de Schulten obtained good crystals of the double salt by mixing a soln. of 28 grms. of diammonium hydrophosphate, 10 grms. of ammonium sulphate, and 12 grms. of phosphoric acid in 80 c.c. of water with a soln. of 16 grms. of heptahydrated magnesium sulphate in 20 c.c. of water. Comparatively large crystals were produced by H. Vohl, O. Richter, and E. Monier by slowly mixing the soln. separated by a permeable diaphragm. A. Millot and L. Maquenne obtained large crystals in acid or neutral soln. in the presence of ammonium citrate; and K. Haushofer from a soln. of the double phosphate in ammonium citrate. R. H. Solly, and A. Arzruni have reported the formation of crystals of struvite in certain culture media for bacteria, and in peptone soln.

M. Berthelot has studied the equilibrium between soln. of magnesium chloride,

and of ammonium phosphate. Hexahydrated magnesium ammonium phosphate is precipitated whenever a neutral magnesium salt is brought in contact with a soln. containing ammonia and phosphoric acid. According to J. J. Berzelius, the salt is slowly precipitated, and the precipitation is never complete unless an excess of phosphate is present in the soln. W. H. Wollaston noticed that the precipitate is deposited on the sides of the glass containing vessel, especially where the stirring rod has scratched it. This salt is usually the form in which magnesium is precipitated in analytical work, and reciprocally also, it is often the form in which phosphoric acid is precipitated. According to H. Neubauer, the precipitation is practically complete even in the presence of comparatively large quantities of ammonium salts, but the composition of the precipitate is largely determined by the nature of the soln., e.g. (i) the precipitate contains a lower proportion of magnesium than the normal phosphate in neutral and ammoniacal soln.; (ii) the precipitate has the normal composition if an excess of the magnesium salt is present; and (iii), the precipitate contains more magnesium than the normal phosphate in the presence of an excess of both magnesium salt and ammonia. R. Reidenbach believes the third observation is not correct, and that the precipitate contains less, not more, magnesium than the normal phosphate.

A. Gawalowsky obtained large crystals with the composition $(\text{NH}_4)_2\text{O} \cdot \frac{1}{2}\text{MgO} \cdot 2\text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$, by crystallization from a soln. of the normal phosphate in acetic acid. The analyses of C. Lindbergson led J. J. Berzelius to assume that another ammonium magnesium phosphate exists containing less magnesium than $\text{NH}_4\text{MgPO}_4 \cdot 6\text{H}_2\text{O}$; and J. Tünnermann supposed the existence of even six varieties of this salt, but T. Graham and G. F. Wach showed that there is only one double magnesium ammonium phosphate. F. A. Gooch and M. Austin have confirmed the existence of a compound $(\text{NH}_4)_2\text{H}_2\text{Mg}(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, whose production is favoured by the presence of an excess of a soluble phosphate or of ammonium salts in the soln. R. W. E. MacIvor reported three minerals in the bat guano of the Skipton Caves (Victoria)—*hannayite*, $\text{Mg}_2\text{H}_2(\text{PO}_4)_2 \cdot \text{MgH}_2(\text{NH}_4)_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, in triclinic crystals with $a:b:c=0.6990:1:0.9743$; *schertelite*, $\text{Mg}(\text{NH}_4)_2\text{H}_2(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$, in small ill-defined crystals; and *dittmarite*, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 2\text{MgH}_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, in rhombic crystals. H. Neubauer and K. Bube also inferred that a compound *magnesium tetrammonium diphosphate*, $\text{Mg}(\text{NH}_4)_4(\text{PO}_4)_2$, i.e. $(\text{NH}_4)_3\text{PO}_4 \cdot \text{Mg}(\text{NH}_4)\text{PO}_4$, is formed in neutral or ammoniacal soln. because, when the precipitate is ignited, some phosphoric acid is volatilized, which is not the case when the normal double salt is ignited under similar conditions. It is assumed that during the ignition of the tetrammonium salt, magnesium metaphosphate is first formed: $\text{Mg}(\text{NH}_4)_4(\text{PO}_4)_2 \rightarrow \text{Mg}(\text{PO}_3)_2 + 4\text{NH}_3 + 2\text{H}_2\text{O}$; and that on further ignition, the metaphosphate decomposes into pyrophosphate and volatile phosphoric oxide: $2\text{Mg}(\text{PO}_3)_2 \rightarrow \text{Mg}_2\text{P}_2\text{O}_7 + \text{P}_2\text{O}_5$.

Disturbances also arise in the presence of alkali salts, so that it is usual to dissolve the precipitate in dil. nitric acid, and reprecipitate it from a soln. which will give the normal phosphate, $\text{NH}_4\text{MgPO}_4 \cdot 6\text{H}_2\text{O}$. Many other observations have been made on this subject by W. Heintz, F. G. Jörgensen, C. Stüinkel, T. Wetzke, and F. Wagner, O. Popp, T. R. Ogilvie, E. W. Parnell, W. Kubel, L. Brünner, etc.

Struvite is sometimes colourless, or it may have a yellowish or brownish tinge. K. Haushofer established the identity of the crystals of struvite and of hexahydrated ammonium magnesium phosphate. According to A. Sadebeck, the pyramidal crystals belong to the rhombic system, and have axial ratios $a:b:c=0.5667:1:0.9121$. H. Haga and F. M. Jäger have studied the X-radiograms of crystals of struvite. E. F. Teschemacher gave 1.65 for the specific gravity of struvite; O. B. Böggild, 1.715; A. de Schulten, 1.711. The hardness is about 2 on Mohs' scale. M. Berthelot gave for the heat of formation of crystalline ammonium magnesium phosphate MgNH_4PO_4 from its elements as 898.8 Cals. The crystals of struvite have a positive double refraction, and, according to O. B. Böggild, the indices of refraction are $\mu_\alpha=1.4954$, $\mu_\beta=1.4963$, and $\mu_\gamma=1.5043$. K. Bube measured the electrical conductivities of aq. soln. of mono- and hexa-hydrated magnesium ammonium phosphate at different temp. K. Hausmann, and E. Kalkowsky have studied the pyroelectrical effects produced by the crystals.

According to C. H. Pfaff, hexahydrated ammonium magnesium phosphate loses ammonia when exposed to air at ordinary temp.; and, according to G. F. Wach,

it loses both water and ammonia when dried for several days in *vacuo* over conc. sulphuric acid. T. Graham reported that when heated to 100° , in a retort, it loses five-sixths of its water of crystallization but no ammonia, while H. Struve maintained, on the contrary, that some ammonia is evolved; L. Chevron and A. Droxhe stated that the residue left on drying at 100° is $\frac{3}{4}\text{NH}_3 \cdot 2\text{MgO} \cdot \text{P}_2\text{O}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. P. Griessmayer reported that the hexahydrate loses some ammonia when boiled with water.

K. Bube found the transition temp. for the conversion of the hexahydrate to **monohydrated ammonium magnesium phosphate**, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot \text{H}_2\text{O}$, under water is between 48° and 49° ; and under its own mother liquid, between 56° and 57° . A. Millot and L. Maquenne boiled equimolar proportions of MgSO_4 and $(\text{NH}_4)_2\text{HPO}_4$, and found that the normal phosphate, $\text{Mg}_3(\text{PO}_4)_2$, is first formed, and that this then takes up ammonia and water, forming plates and cubes of the monohydrate, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot \text{H}_2\text{O}$. The crystals are not doubly refracting, they remain unchanged at 100° , and dissolve neither in water nor in a soln. of ammonium citrate.

According to A. F. de Fourcroy and J. J. Berzelius, when hexahydrated ammonium magnesium phosphate is strongly heated, it loses all its ammonia and water and is reduced to a powder which fuses at a higher temp. forming a clear glass of magnesium pyrophosphate; if, when all the water and ammonia have been expelled at a moderate heat, the residue be subsequently exposed to a greater degree of heat, it becomes slightly incandescent in consequence of an intramolecular change—according to O. Popp, owing to the passage of the pyrophosphate from a crystalline to an amorphous condition—because no change in weight can be detected before and after the material has glowed. H. Struve, and O. Popp found that the incandescence occurs if the magnesium pyrophosphate be contaminated with calcium or other magnesium compounds, and, particularly so, with silica. Analyses confirmatory of the conversion of the double salt into magnesium pyrophosphate: $2\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O} \rightarrow \text{Mg}_2\text{P}_2\text{O}_7 + 2\text{NH}_3 + 13\text{H}_2\text{O}$, were made by G. F. Wach, A. Riffault, C. Lindbergson, J. J. Bergson, F. Stromeyer, C. H. Pfaff, etc. The hexahydrated magnesium ammonium phosphate precipitated in analysis is weighed as magnesium pyrophosphate.

J. J. Berzelius said that hexahydrated ammonium magnesium phosphate is slightly soluble in water, and C. R. Fresenius found that a litre of **water** at 10° dissolves 0.065 grm. of ammonium magnesium phosphate. E. Ebermayer gave 0.074 grm. per litre at 20.5° – 22.5° ; J. von Liebig gave 0.107 grm.; and J. A. Völcker, 0.106 grm. P. Wenger gave for the solubility of NH_4MgPO_4 in grams per litre at different temp.:

	0°	20°	40°	50°	60°	70°	80°
NH_4MgPO_4	0.023	0.052	0.036	0.030	0.040	0.016	0.019

The irregularity in the results shows that equilibrium was not attained. The results are also probably complicated by hydrolysis, and by the transition from the hexa- to the mono-hydrate. K. Bube also measured the solubility of the mono- and hexa-hydrates in water. The double salt is much less soluble in water containing *ammonia*, thus, C. R. Fresenius found a litre of an aq. soln. of ammonia dissolves 0.0226 grm. of the double salt; while, according to F. G. Jörgensen, the solubility of the double salt in $2\frac{1}{2}$ per cent. aq. ammonia is approximately eq. to 0.0006 grm. MgO per litre; and, according to C. Stünkel, T. Wetzke, and F. Wagner aq. soln. of 1, 2, and 3 per cent. ammonia dissolve respectively the eq. of 0.00050, 0.00023, and 0.00008 grm. of MgO . E. Ebermayer found that between 20.5° and 22.5° , a litre of aq. ammonia dissolves:

Per cent. NH_3	0	1.98	2.48	4.95	6.64	7.43	9.91
Grm. $(\text{NH}_4)\text{MgPO}_4$	0.0741	0.0322	0.0272	0.0232	0.0221	0.0191	0.0164

The solubility increases with rise of temp. Expressing the results in grams of NH_4MgPO_4 per 1000 grms. of a mixture of one part aq. ammonia (sp. gr. 0.96) and 4 parts of water, P. Wenger found:

	0°	20°	40°	50°	60°	70°	80°
$(\text{NH}_4)\text{MgPO}_4$	0.087	0.098	0.136	0.153	0.174	0.178	0.145

The decrease in the solubility at the higher temp. may be connected with the transition from the hexa- to the mono-hydrate. C. R. Fresenius found the double salt is more soluble in the presence of 20 per cent. *ammonium chloride*, for a litre of the soln. dissolved 0.132 grm. of the double salt. F. G. Jörgensen also noted that the solubility of the double salt is increased in the presence of ammonium chloride, so that a litre of 2½ per cent. ammonia with a gram of ammonium chloride dissolves the eq. of 0.013 grm. of MgO. P. Wenger gives for the solubility of the double salt in a 5 per cent. soln. of ammonium chloride, in grams of NH_4MgPO_4 per 1000 grms. of solvent:

	0°	20°	30°	40°	50°	60°	70°	80°
NH_4MgPO_4 . . .	0.60	1.05	1.13	0.71	0.93	1.73	1.24	1.91

Here again there is every indication that equilibrium was not attained. When the ammonium chloride soln. of the double salt is boiled, K. Kraut found that ammonia is evolved. According to C. R. Fresenius, a litre of a soln. of ammonium chloride and ammonia dissolved 0.064 grm. of the double salt; P. Wenger from 100 grms. of a 5 per cent. soln. of ammonium chloride with 4 of ammonia per 100 dissolved 0.165 and 0.274 grm. per litre at 20° and 60°. P. Wenger's values for the solubilities of the double salt in a 5 per cent. soln. of *ammonium nitrate* resemble those with ammonium chloride:

	0°	20°	30°	40°	50°	60°	70°	80°
NH_4MgPO_4 . . .	1.10	0.46	0.54	0.64	0.72	0.85	0.83	1.01

J. von Liebig found that an aq. soln. of *ammonium sulphate* containing 2.2, 3.0, and 10 grms. $(\text{NH}_4)_2\text{SO}_4$ per litre, dissolved respectively 0.0717, 0.1130, and 0.147 grm. of the double salt. A. Bolis found that 2 grms. of hexahydrated ammonium magnesium phosphate in contact with 100 c.c. of a soln. of *ammonium citrate* (400 grms. citric acid per litre) loses, by soln., 0.457 per cent. in weight at ordinary temp., and 0.587 per cent. at 50°. A. Millot found a boiling soln. of ammonium citrate dissolves the double salt, which re-crystallizes out on cooling. J. Ville noted that a soln. of ammonium citrate dissolves only traces of the double salt, while soln. of *calcium citrate* dissolve larger amounts. J. von Liebig found that water containing 2 grms. of *sodium chloride* per litre dissolves 0.1234 grm. of the double salt per litre, and an aq. soln. containing 3 grms. of *sodium nitrate* per litre dissolves 0.0931 grm. of the double salt. When the double salt is precipitated in the presence of alkali salts, the latter are occluded or adsorbed and the resulting increase in weight more than counterbalances the solubility losses.

Hexahydrated ammonium magnesium phosphate is readily soluble in **acetic acid** and in other dil. acids, and, as C. H. Pfaff showed, the dissolution is accompanied by partial decomposition. J. von Liebig found a litre of water sat. with **carbonic acid** dissolves 1.425 grms. of the double salt; B. W. Gerland studied the solubility of the double salt in **sulphurous acid**. According to A. Marcet, a soln. of the double salt in **hydrochloric acid**, when evaporated to dryness and heated, furnishes a sublimate of ammonium chloride. When digested with **glycerol**, especially at an elevated temp., the ammonium double salt is converted into magnesium hydrophosphate. According to M. Märcker, and P. Griessmayer, when the double salt is boiled with magnesium oxide, part of the ammonia is expelled; and C. H. Pfaff found that the **fixed alkalies** liberate ammonia from the double salt, although H. Rose found the salt is but incompletely decomposed by **alkali carbonates**. C. H. Pfaff found that when ignited with **carbon**, some phosphorus is evolved. H. Struve, and R. Weber found that when ignited in the presence of **reducing agents**—e.g. carbon, hydrogen, unburnt gases from the source of heat, etc.—at a high temp., phosphorus, phosphorus oxide, or hydride are evolved, and, as shown by W. C. Heraeus, W. P. Headen, etc., these vapours attack the platinum crucible.

A rare mineral found in the quartz and clay slate of Höligraben in Salzburg (Austria), and having a superficial resemblance to topaz,⁴ was shown by J. N. von Fuchs to be a magnesium fluophosphate, and was named *wagnerite*. A. Breithaupt

called it *pleuroclase*. Analyses by J. N. von Fuchs, and C. F. Rammelsberg are in agreement with the formula, $\text{Mg}_3(\text{PO}_4)_2 \cdot \text{MgF}_2$. P. Groth regards it as a salt of orthophosphoric acid, $\text{Mg}(\text{MgF})\text{PO}_4$; and G. Tschermak as a salt of HMg_2PO_4 , namely, $\text{Mg}_2\text{F} \cdot \text{PO}_4$, in which the hydrogen can be replaced by fluorine :

Monoclinic crystals, with a composition approximating to wagnerite, were found by A. Scacchi near Massa di Somma and San Sebastiano (Vesuvius), and regarded as a distinct mineral species which was called *cryphiolite*; but F. Zambonini showed that cryphiolite and wagnerite are really the same. F. von Kobell found a mineral at Kjerulfen, near Bambe (Norway), which he regarded as $2\text{Mg}_3(\text{PO}_4)_2 \cdot \text{CaF}_2$, and named *kjerulfine*, but G. C. Wittstein, M. Bauer, and W. C. Brögger and E. Reusch showed that the optical properties of kjerulfine are identical with those of wagnerite, and this conclusion is in agreement with analyses by F. Pisani, C. F. Rammelsberg, F. Friederici, etc. It is probable that calcium can replace magnesium in wagnerite, forming *calcium-wagnerite*, and these have been synthesized by H. St. C. Deville and H. Caron, etc. H. Winter prepared *strontium-wagnerite* and *barium-wagnerite*. H. St. C. Deville and H. Caron also prepared *chloro-wagnerite* in which the fluorine is replaced by chlorine; and *ferro-wagnerite* and *manganowagnerite*, where ferrous oxide and manganous oxide respectively replace the magnesium oxide of normal wagnerite. A. Ditte has made an analogous series of *bromo-wagnerite*; while H. Debray, and H. Lechartier prepared *arsenico-wagnerite*, and P. Hautefeuille, *vanadium wagnerite*.

In H. St. C. Deville and H. Caron's synthesis of normal wagnerite, 132 parts of ammonium dihydrophosphate and 60 parts of magnesium fluoride were heated with a great excess of magnesium chloride in a carbon crucible at a red heat. The soluble matter was leached with water from the cold mass; by fusing one part of calcium fluoride with ten parts of normal magnesium phosphate and a large excess of calcium chloride, calcium chloro-wagnerite was formed: $(\text{Ca}, \text{Mg})_3(\text{PO}_4)_2 \cdot (\text{Ca}, \text{Mg})(\text{F}, \text{Cl})_2$. H. Winter made wagnerite by melting equimolar parts of normal magnesium phosphate and magnesium fluoride.

The colour of wagnerite is yellowish- or reddish-white. The prismatic crystals are holohedral, and belong to the monoclinic system with axial ratios $a : b : c = 1.9145 : 1 : 1.5059$, and $\beta = 71^\circ 53'$. The **specific gravity** is 3.07 to 3.15; J. N. von Fuchs gave 3.13 at 15° ; C. F. Rammelsberg, 3.026 at 15° ; F. Pisani, 3.12; F. von Kobell, 3.15; and H. St. C. Deville and H. Caron, 3.12 for artificial wagnerite. The **hardness** is 5 to $5\frac{1}{2}$. Wagnerite fuses in the blowpipe flame to a grey glass. The **double refraction** is negative; the dispersion feeble; and, according to M. Levy and A. Lacroix, the **indices of refraction** are $\alpha = 1.569$; $\beta = 1.570$; and $\gamma = 1.582$. The mineral is soluble in nitric and hydrochloric acids.

§ 21. Magnesium Hydrophosphates

Anhydrous magnesium hydrophosphate, MgHPO_4 , has not been made, but four hydrates have been reported, $\text{MgHPO}_4 \cdot n\text{H}_2\text{O}$, where n is 1, 3, $4\frac{1}{2}$, or 7. Magnesium hydrophosphate occurs in human faeces; and trihydrated magnesium hydrophosphate occurs as a guano mineral, *newberyite*. A specimen of the latter from the bat guano in the Skipton Caves (Victoria), was reported by G. vom Rath,¹ and R. W. E. MacIvor; while a mineral, which appeared to be a mixture of newberyite and struvite, from Quarz Creek (Dawson City, Yukon), was analyzed by G. C. Hoffmann.

A. de Schulten² obtained microscopic crystals of **monohydrated magnesium hydrophosphate**, $\text{MgHPO}_4 \cdot \text{H}_2\text{O}$, by heating a soln. of magnesium carbonate in an excess of phosphoric acid for some hours in a sealed tube at 225° . A. F. de Fourcroy, A. Riffault, T. Graham, L. Schaffner, and C. G. Reischauer prepared **trihydrated magnesium hydrophosphate**, $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$, in needle-like crystals, by the mixing of a soln. of, say, 2 parts of magnesium sulphate in 32 parts of water, with 3 parts of decahydrated disodium hydrophosphate in 32 parts of water, and allowing the soln. to stand 24 hrs. at a temp. above 36° . H. Rose stated that if very dil. soln. are employed, the normal phosphate is produced. H. Debray made this compound by neutralizing an aq. soln. of phosphoric acid with magnesium carbonate, the precipitated heptahydrate was filtered off. On boiling the filtrate, small crystals of this salt separated from the soln. H. Struve added that only the trihydrate is produced if the boiling soln. of phosphoric acid is treated with magnesium oxide or carbonate, until the liquid has only a feeble acid reaction. J. Stocklasa made the trihydrate by heating dihydrated magnesium tetrahydrophosphate in the solid state or in alcoholic soln. at 100° . B. W. Gerland also made the trihydrate from a soln. of the normal phosphate in sulphurous acid. A. de Schulten mixed a soln. of 16 grms. of heptahydrated magnesium sulphate in 120 c.c. of water with a soln. of 20 grms. of diammonium hydrophosphate, 10 grms. of ammonium sulphate, and 12 grms. of phosphoric acid in 80 c.c. of water, and in 24 hrs. obtained crystals of struvite, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O}$, which when left in contact with the mother liquid did not change; but when a more conc. soln. of the magnesium sulphate was employed, a mixture of crystals of struvite and newberyite, $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$, was formed, and when allowed to stand in contact with the mother liquid, the latter increased at the expense of the former.

According to F. K. Cameron and J. M. Bell, when mixtures of phosphoric acid and magnesium oxide are agitated for two months, the clear soln. contains, per litre, at 25° ,

MgO	0.207	2.23	26.09	75.5	122.6	146	160	87.1	70.6
P ₂ O ₅	0.486	7.35	93.09	281.8	498	623	700	779.6	835.1
Sp. gr.	—	1.006	1.109	1.285	1.470	1.595	—	1.626	1.654

Solid phases

 $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$ $\text{Mg}(\text{H}_2\text{PO}_4) \cdot n\text{H}_2\text{O}$

The graph of the results is shown in Fig. 29 in connection with magnesium dihydrophosphate.

H. Debray claimed to have made crystals of **enneahemihydrated magnesium hydrophosphate**, $\text{MgHPO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, by allowing magnesium carbonate to stand for some days in contact with phosphoric acid. A. F. de Fourcroy, T. Graham, C. G. Reischauer, A. Riffault, and L. Schaffner prepared **heptahydrated magnesium hydrophosphate**, $\text{MgHPO}_4 \cdot 7\text{H}_2\text{O}$, by the process employed for the trihydrate, but keeping the mixture at a temp. below 36° . T. Bergmann probably also made this salt by evaporating a soln. of magnesium oxide in phosphoric acid, and J. J. Berzelius by evaporating a mixed soln. of magnesium acetate and phosphoric acid. L. Chevron and A. Droixhe prepared the heptahydrate by digesting a soln. of potassium dihydrophosphate with magnesium oxide or hydroxide, and allowing the filtered soln. to stand at ordinary temp. According to J. Percy,

the amorphous precipitate of the heptahydrate becomes crystalline when exposed to the action of carbon dioxide.

The **crystals** of the monohydrate were stated by A. de Schulten to behave in polarized light as if they belonged to the rhombic system, but that they are really monoclinic twinned complexes, and resemble the trihydrated pyrophosphate. The trihydrate forms acicular crystals or rhombic six-sided plates, which, in the natural state, according to A. Schmidt, belong to the rhombic system, and have the axial ratios $a : b : c = 0.9548 : 1 : 0.9360$. The heptahydrate also forms small six-sided columnar or acicular crystals which, according to K. Haushofer, are monoclinic prisms with axial ratios $a : b : c = 0.4451 : 1 : 0.2177$, and $\beta = 94^\circ 18'$. A. de Schulten found that the **specific gravity** of the monohydrate is 2.326 at 15° ; the natural trihydrate, according to A. Schmidt, has a sp. gr. 2.10, and **hardness** 3.

FIG. 29.—Equilibrium between Magnesium Oxide and Phosphoric Acid in Aqueous Solutions at 25° .

A. de Schulten stated that the monohydrate loses no water when heated to 100° . According to H. Struve, the trihydrate loses water when heated above 100° , while T. Graham found that the trihydrate loses its water of crystallization at 170° , and at a higher temp. it forms the pyrophosphate. T. Graham, and L. Schaffner found that the heptahydrate rapidly effloresces in dry air, and loses three-sevenths of its water of crystallization at 100° , and at a higher temp. the pyrophosphate is formed; according to A. F. de Fourcroy, the salt melts to a transparent glass when heated to a still higher temp. H. Struve found that the heptahydrate, according to the mode of preparation, loses 4 to 4.5 mols of water at 100° . C. G. Reischauer stated that when the heptahydrate, dried over sulphuric acid, is heated in a closed vessel, it passes into the trihydrate, and appears to become moist; but the undried heptahydrate loses 5.5 mols over sulphuric acid, and the product does not absorb quite enough water to produce the trihydrate when it is exposed to moist air. According to M. Berthelot, the **heat of formation** of crystalline $MgHPO_4$ from its elements is 413.6 Cals., and from magnesium sulphate and disodium hydrogen phosphate is -0.79 Cal. when the amorphous salt is produced, and when this becomes crystalline, 1.80 Cals. are set free, so that the total heat of formation of the crystalline salt is 1.01 Cals. The **heat of neutralization** of phosphoric acid with magnesium hydroxide to form $MgHPO_4$ is 25.30 or 27.10 Cals. depending on whether the amorphous or crystalline salt is produced. A. Schmidt found newberyite has the **index of refraction** $\mu_B = 1.5196$ for Na-light, and the **double refraction** is positive. P. Bary stated that the heptahydrate does not fluoresce either in **X-rays** or in **Becquerel's rays**.

According to H. Struve, 100 parts of water dissolve 0.025 part of the trihydrate; and F. Graham found that after several days' digestion 100 parts of cold water dissolve 0.3106 part of the heptahydrate; the soln. becomes turbid at 49° , and milky at 100° in consequence of the separation of the unchanged salt; a boiling sat. soln. contains 0.2008 part of the salt in 100 parts of water. Any salt which has been deposited from the soln. by raising the temp., is re-deposited on cooling. L. Schaffner found that digestion with boiling water frequently renewed converts the hydrophosphate into the normal salt (*q.v.*), and the soln. contains the dihydrophosphate, $Mg(H_2PO_4)_2$. H. Debray also heated the hydrophosphate with water in a sealed tube at 120° , and obtained the normal salt. A. Riffault, however, said that boiling water decomposes the hydrophosphate into a soluble acid salt and an

insoluble basic salt. According to T. Graham, magnesium hydrophosphate is much more soluble in water containing a trace of one of the acids—phosphoric, sulphuric, hydrochloric, nitric, oxalic, or acetic acid—and the soln. thus obtained does not become turbid when boiled. *Vide supra* for B. W. Gerland's observations on the solubility of magnesium hydrophosphate in **sulphurous acid**. C. A. Lesueur found that precipitated hydrophosphate absorbs **ammonia**, and is transformed into ammonium magnesium phosphate; A. Pavesi and E. Rotondi said that the absorption is incomplete; and H. Iutschak, that the precipitate dried at 100° does not absorb ammonia. According to A. Joannis, when magnesium hydrophosphate is left for three days in contact with liquid ammonia, only an insignificant amount is absorbed.

J. Stoklasa³ prepared **dihydrated magnesium dihydrophosphate**, $\text{Mg}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, by digesting on a water-bath magnesium oxide in a conc. soln. of phosphoric acid of sp. gr. 1.4, so that the product contains from 5 to 7 per cent. of free phosphoric acid; the soln. is evaporated until crystallization begins, then cooled, and the crystals washed with ether, pressed between filter-paper, again washed with ether until no more phosphoric acid is removed, and then dried in a stream of air. F. K. Cameron and J. M. Bell treated trihydrated magnesium hydrophosphate with soln. of phosphoric acid of varying conc. The stable solid in contact with the more dil. soln. is $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$, but with conc. soln. containing over 700 grms. P_2O_5 per litre, the solid phase is $\text{Mg}(\text{H}_2\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$. The observed results are indicated in connection with magnesium hydrophosphate. For soln. in contact with magnesium hypophosphate the proportion of magnesium oxide in soln. increases regularly with increased conc. of phosphoric acid, whilst for those in equilibrium with the latter salt, the conc. of magnesium oxide diminishes with increasing phosphoric acid conc. Some evidence has been obtained that a magnesium phosphate more basic than the diphosphate exists at 25° in contact with very dil. soln. of phosphoric acid.

The radial aggregates of the crystals are not particularly hygroscopic, they absorb about one per cent. of water from the air of a room, and from an atm. sat. with water-vapour, in 24 hrs. 6–7 per cent. of water which is given off again in dry air. When dehydrated at 100°–170°, J. Stoklasa found that anhydrous **magnesium dihydrophosphate**, $\text{Mg}(\text{H}_2\text{PO}_4)_2$, is formed as a white opaque crystalline mass, which remains unchanged in air, and is non-hygroscopic. At 175°, the dihydrophosphate decomposes: $4\text{Mg}(\text{H}_2\text{PO}_4)_2 = 3\text{Mg}(\text{H}_2\text{PO}_4)_2 + \text{MgH}_2\text{P}_2\text{O}_7 + \text{H}_2\text{O}$; at 184°, $4\text{Mg}(\text{H}_2\text{PO}_4)_2 = 2\text{Mg}(\text{H}_2\text{PO}_4)_2 + 2\text{MgH}_2\text{P}_2\text{O}_7 + 2\text{H}_2\text{O}$; at 196°, $4\text{Mg}(\text{H}_2\text{PO}_4)_2 = \text{Mg}(\text{H}_2\text{PO}_4)_2 + 3\text{MgH}_2\text{P}_2\text{O}_7 + 3\text{H}_2\text{O}$; and at 205°, $4\text{Mg}(\text{H}_2\text{PO}_4)_2 = 4\text{MgH}_2\text{P}_2\text{O}_7 + 4\text{H}_2\text{O}$ —*vide infra* for the dihydropyrophosphate—100 c.c. of water dissolve 20 grms. of anhydrous dihydrophosphate, without decomposition, and thus the behaviour is different from the corresponding calcium salt; nor does an aq. soln. of magnesium dihydrophosphate decompose at 60°; but with alcohol the salt is decomposed: $\text{Mg}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O} + \text{H}_2\text{O} = \text{MgHPO}_4 \cdot 3\text{H}_2\text{O} + \text{H}_3\text{PO}_4$; the reaction progresses rapidly at 100°, and with a great excess of alcohol is quantitative.

§ 22. Magnesium Pyrophosphates

When magnesium hydrophosphate or ammonium magnesium phosphate is heated, normal **magnesium pyrophosphate**, $\text{Mg}_2\text{P}_2\text{O}_7$, remains as a transparent glass. Z. Karaoglanoff and P. Dimitroff¹ found that if the ammonium magnesium phosphate is precipitated slowly while boiling, the conversion to pyrophosphate by ignition is not attended by incandescence; the converse obtains if the salt is precipitated rapidly at a lower temp. Traces of organic matter are also necessary for the incandescent effect. According to H. Rose, an aq. soln. of pyrophosphoric acid gives a precipitate of **trihydrated magnesium pyrophosphate**, $\text{Mg}_2\text{P}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$ —according to the analyses of the crystalline and amorphous salts by A. Schwarzenberg—when added to a soln. of magnesium sulphate in the presence of ammonium chloride and ammonia; this salt is soluble in much water; while normal sodium pyrophosphate gives a precipitate with magnesium sulphate which is soluble in an excess of both agents; when the mixture is boiled, a precipitate again forms which does not redissolve on cooling. G. F. Wach stated that sodium dihydropyrophosphate gives no precipitate with magnesium sulphate until further addition of ammonium carbonate, and the precipitate which is then formed contains but a trace of ammonia, and is dissolved by an excess of either magnesium sulphate or the sodium dihydropyrophosphate. According to A. Schwarzenberg, when a soln. of magnesium oxide in one of sodium dihydropyrophosphate is heated, gelatinous magnesium pyrophosphate, resembling aluminium hydroxide, separates out; when this is dissolved in sulphurous acid, and boiled, it appears as a crystalline powder.

O. Andersen found that colourless glass-like **tabular crystals** were readily obtained by cooling fused magnesium pyrophosphate; the monoclinic crystals have the axial ratios $a:b:c=0.7947:1:1.0880$, and $\beta=75^\circ 49'$. By twinning, the crystals often approximate to the rhombic form. Z. Karaoglanoff and P. Dimitroff said that if the pyrophosphate is produced with incandescence by the ignition of ammonium magnesium phosphate, it is hard, grey to black, and lava-like; if not produced with incandescence, it is an amorphous powder, loose in texture. F. W. Clarke found the **specific gravity** of the anhydrous, probably amorphous, normal pyrophosphate is 2.559 at 18° , and 2.598 at 22° ; H. G. F. Schröder gave 2.20. O. Andersen showed that the crystals have a sp. gr. 3.058 at $25^\circ/4^\circ$. The **hardness** is a little below 4. A. Schwarzenberg noted that both the amorphous and crystalline salt lose all the water of crystallization at 100° . O. Andersen measured the **indices of refraction** for Na-light, and found $\mu_\alpha=1.615 \pm 0.003$; $\mu_\beta=1.604 \pm 0.003$; $\mu_\gamma=1.602 \pm 0.003$; and the maximum positive **double refraction** is $\alpha-\gamma=0.013 \pm 0.005$. P. Bary stated that the salt does not fluoresce when exposed to the **X-rays**, or to **Becquerel's rays**.

H. Struve found that when heated white hot in a stream of **hydrogen**, magnesium pyrophosphate is reduced developing phosphorus and phosphine. C. R. Fresenius stated that the salt is easily soluble in **hydrochloric acid**; while T. Graham said that it is dissolved with difficulty by that acid. According to R. Weber, and C. R. Fresenius, magnesium pyrophosphate is not completely precipitated as ammonium magnesium phosphate, when the acid soln. is neutralized with ammonia. R. Weber stated that when boiled with **sulphuric acid**, it is converted into the normal salt, while H. Pellet stated that it is transformed into *magnesium pyrosulphophosphate*. Magnesium pyrophosphate is readily dissolved in nitric acid, and the soln. behaves towards ammonia like the soln. in hydrochloric acid. According to D. Campbell,

the soln. in **nitric acid** furnishes crystals of magnesium nitrate when evaporated to a syrupy consistence by standing over conc. sulphuric acid; and, according to E. Luck, if the soln. is evaporated to complete dryness, a white gum-like mass remains which has an acid reaction, and which is regarded by D. Campbell, and E. Luck, as a magnesium nitritophosphate, $2\text{MgO} \cdot \text{H}_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot \text{NO}_2$. H. Rose found that the pyrophosphate is completely converted into the normal phosphate by fusion with **sodium carbonate**.

According to J. Stoklasa, when magnesium dihydrophosphate is heated to 205° , **magnesium dihydroxyphosphate**, $\text{MgH}_2\text{P}_2\text{O}_7$, is formed; and he also found when $\text{Mg}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ is heated for 2 hrs. at

	210°	220°	240°	260°	280°	295°	303°
Per cent. loss . . .	22.4	22.42	23.28	23.64	23.66	26.99	23.50

The calculated loss for the formation of $\text{MgH}_2\text{P}_2\text{O}_7$ is 21.26 per cent. and for $\text{Mg}(\text{PO}_3)_2$, 28.35 per cent.

A. Beer, and H. Ludwig prepared **sodium magnesium pyrophosphate** by gradually adding magnesium chloride to a boiling soln. of sodium pyrophosphate. The amorphous precipitate is washed with water containing ammonia. The precipitate is soluble in water, and readily soluble in hydrochloric or nitric acid; J. F. Persoz, and A. Schwarzenberg obtained a similar precipitate which dissolved in an excess of the sodium pyrophosphate furnishing a liquid which soon became turbid and congealed to a gelatinous solid on standing. L. Ouvrard obtained crystals of $\text{Na}_2\text{MgP}_2\text{O}_7$ by slowly cooling a soln. of magnesium oxide, chloride, or phosphate in fused sodium orthophosphate or pyrophosphate, and extracting the mass with water. The dendritic crystals probably belong to the cubic system; their sp. gr. is 2.2 at 20° . K. A. Wallroth obtained transparent prisms with the composition $\text{Mg}_{10}\text{Na}_{16}(\text{P}_2\text{O}_7)_9$ by dissolving the metallic oxide in microcosmic salt heated to a bright red heat; the glass so formed is maintained in a state of fusion until the crystals have separated out. On cooling, the mass is digested with water, and then with dil. hydrochloric acid. L. Ouvrard obtained the same compound. The transparent prisms are probably monoclinic; their sp. gr. is 2.7 at 20° ; they fuse to a transparent glass; and are readily soluble in acids. M. Berthelot and G. André prepared the triple salt **ammonium sodium magnesium pyrophosphate**, $(\text{NH}_4)_3\text{NaMg}_6(\text{P}_2\text{O}_7)_4$, by precipitation from a soln. of normal sodium pyrophosphate with magnesia mixture; the precipitate is dissolved by adding a great excess of ammonium chloride, and the soln. acidified with acetic acid. When boiled for a long time, the compound in question separates out. It is insoluble in, and undecomposed by water; but a prolonged washing with acetic acid extracts magnesium. No ammonia is lost at 110° . There is doubt about the individuality of these products.

T. Fleitmann and W. Henneberg^{*} prepared **magnesium tetrphosphate**, $3\text{MgO} \cdot 2\text{P}_2\text{O}_5$, by precipitation from a soln. of magnesium sulphate by adding the sodium salt; or by fusing together the salts and leaching the product with water. The white insoluble crystalline powder becomes insoluble in acids when heated to a high enough temp. M. Stange prepared **sodium magnesium triphosphate**, $\text{Na}_3\text{MgP}_3\text{O}_{10} \cdot 13\text{H}_2\text{O}$, by adding a soln. of magnesium chloride to one of sodium triphosphate until a permanent precipitate begins to form; this is quickly redissolved by the addition of sufficient triphosphate, and the salt then at once commences to separate. It crystallizes in very slender needles, is decomposed by exposure to air, losing water of crystallization, and, when heated, intumesces like borax, and melts at a red heat to a clear glass easily soluble in acids.

§ 23. Magnesium Metaphosphates

According to R. Maddrell,¹ **magnesium metaphosphate** is formed by dissolving magnesium carbonate in an excess of dil. phosphoric acid, evaporating the soln. to dryness, and heating the residue to 316°; or, according to J. Stoklasa, by heating magnesium dihydrophosphate to 305°. It appears as a glassy mass, which, according to T. Fleitmann, is not changed by digestion for a day with soln. of alkali carbonate or phosphate, and it is therefore not clear to which particular metaphosphate this product belongs.

A. Glatzel made anhydrous **magnesium dimetaphosphate**, MgP_2O_6 , by evaporating a soln. of magnesium carbonate in aq. phosphoric acid, with about one per cent. in excess, first on a water-bath, then on a sand-bath, and finally at 400°. The pulverized mass was washed with cold water slightly acidified with nitric acid. The resulting crystalline powder is strongly attacked by sulphuric, nitric, or hydrochloric acid. T. Fleitmann prepared **hydrated magnesium dimetaphosphate**, $\text{MgP}_2\text{O}_6 \cdot n\text{H}_2\text{O}$ —where $n=4$ according to A. Glatzel, and 4.5 according to T. Fleitmann—by mixing conc. soln. of his ammonium dimetaphosphate, $(\text{NH}_4)_2\text{P}_2\text{O}_6$, with an excess of magnesium chloride, and allowing the mixture to stand for some time. The resulting crystals do not dissolve in water, and are not decomposed by acids; but conc. sulphuric acid was found by A. Glatzel to dissolve readily the salt, forming, when boiled, normal phosphoric acid. T. Fleitmann found that the calcined salt is not changed by soln. of alkali carbonates or phosphates. At 100°, the hydrated salt loses about 2 per cent. of water, and the remainder on calcination. T. Fleitmann stated that some phosphoric oxide is lost at the same time, but A. Glatzel said that this is wrong.

A. Glatzel prepared tetrahydrated **sodium magnesium dimetaphosphate**, $\text{Na}_2\text{Mg}(\text{P}_2\text{O}_6)_2 \cdot 4\text{H}_2\text{O}$, as a crystalline powder by mixing conc. soln. of sodium dimetaphosphate and magnesium chloride. The complex salt loses its water of crystallization completely at a dull red heat, sinters at a higher temp., and passes without melting into polymerized phosphoric acid. Before calcination, the salt is readily soluble in sulphuric, hydrochloric, and nitric acids, but after conc., it is soluble only in conc. sulphuric acid. 100 c.c. of water dissolve 4 grms. of the salt. A. Glatzel prepared the corresponding tetrahydrated **potassium magnesium dimetaphosphate**, $\text{K}_2\text{Mg}(\text{P}_2\text{O}_6)_2 \cdot 4\text{H}_2\text{O}$, in a manner similar to that employed for the sodium salt. It loses its water of crystallization at 150°, and after heating to redness, it is not affected by soln. of alkali carbonates. It does not fuse at a bright red heat. 100 parts of water dissolve 9.84 parts of salt. The salt is readily decomposed by acids—particularly boiling sulphuric acid—forming phosphoric acid. According to L. Ouvrard, when magnesia is dissolved in potassium metaphosphate, the sole product is the compound $\text{K}_2\text{Mg}_2(\text{P}_2\text{O}_6)_3$, which crystallizes in large, monoclinic prisms, very soluble in dil. acids; sp. gr. at 20°=2.4. It is analogous to the double magnesium sodium phosphate obtained by T. Fleitmann and W. Henneberg in the wet way.

T. Fleitmann prepared hydrated **ammonium magnesium dimetaphosphate**, $(\text{NH}_4)_2\text{Mg}(\text{P}_2\text{O}_6)_2 \cdot n\text{H}_2\text{O}$, by mixing soln. of ammonium dimetaphosphate and magnesium chloride. A. Glatzel found the crystals lose all their water at 150° . T. Fleitmann said that the hydrate contains 6 mols of water, and effloresces in air; *au contraire*, A. Glatzel said the crystals contain 4 mols of water, and do not lose weight even when confined over conc. sulphuric acid. The latter also stated that the crystals lose ammonia at a dull red heat, and at a bright red heat, phosphoric oxide; at a still higher temp. the product melts and forms magnesium tetrametaphosphate. The double salt is easily attacked by acids.

According to G. F. Wach, when a soln. of recently ignited metaphosphoric acid in aq. ammonia is added to one of magnesium sulphate, the precipitate first formed is redissolved so long as an excess of the latter is present, but when the former is in excess, the precipitate remains undissolved. Alcohol precipitates the portion still remaining in soln. An excess of magnesium chloride, nitrate, or acetate gives the same precipitate, but does not dissolve it so readily. The precipitate forms feathery flakes which unite to form a stringy viscid mass which, after being washed with water and dried, becomes transparent and brittle like glass. When the product is heated in a glass tube, it swells up, forming an opaque spongy mass with the evolution of water at first, and afterwards ammonia. The residue does not fuse at the temp. at which glass softens; it dissolves in water with difficulty to form a soln. with an acid reaction, but is itself slightly soluble in acids. The undecomposed double salt dissolves somewhat freely in cold water, but is precipitated on the addition of alcohol. The cold soln. has an acid reaction towards litmus, and deposits the salt as a viscid mass, when heated, but re-dissolves it on cooling. In boiling water, the salt swells to an opaque frothy mass, without any considerable proportion passing into soln. The analyses of the double salt do not correspond with a definite magnesium ammonium meta- or pyro-phosphate.

G. Tammann has argued that the so-called magnesium dimetaphosphate is really **hydrated magnesium trimetaphosphate**, $\text{Mg}_3(\text{P}_3\text{O}_9)_2 \cdot 14\text{H}_2\text{O}$. C. G. Lindbom prepared dodeca- and pentadeca-hydrated trimetaphosphates by crystallization from a mixed soln. of two parts of hexahydrated magnesium chloride, and one part of sodium trimetaphosphate, at 20° to 30° —either the one or the other hydrate appears. When the crystals are dried on the water-bath they retain about 10.5 mols of water, which is all lost at a red heat, without melting. The residue is insoluble in boiling hydrochloric acid. The salt is sparingly soluble in water, and the soln. is neutral. When the aq. soln. is treated with aq. ammonia and normal sodium phosphate, the salt is precipitated. T. Fleitmann and W. Henneberg, and C. G. Lindbom have prepared sodium magnesium trimetaphosphate, $\text{Na}_4\text{Mg}(\text{P}_3\text{O}_9)_2 \cdot 5\text{H}_2\text{O}$. The latter evaporated a mixed soln. of hexahydrated magnesium chloride with about four times its weight of sodium trimetaphosphate at 20° to 30° , and obtained a crystalline crust, which was washed with a little water. Over conc. sulphuric acid, about one-tenth of the water of crystallization was removed, and all was expelled at a high temp. The product melts at a red heat, forming an opaque white mass which deliquesces in air, and furnishes a soln. of sodium hexametaphosphate when treated with water, and magnesium metaphosphate remains. The double salt dissolves slowly in water, the soln. is neutral, and is not precipitated by sodium carbonate or disodium hydrophosphate unless ammonia has been previously added.

According to A. Glatzel, when magnesium dimetaphosphate is melted, and slowly cooled, **magnesium tetrametaphosphate**, $\text{Mg}_2\text{P}_4\text{O}_{12}$, is formed. The salt crystallizes in stellate aggregates. It is insoluble in water, and is attacked by hydrochloric acid, still more by nitric acid, and quite vigorously by conc. sulphuric acid. When digested for a day with a soln. of alkali carbonate, the alkali tetrametaphosphate is formed. When a dil. soln. of ammonium tetrametaphosphate is treated with an excess of magnesium chloride, small white crystals of **decahydrated magnesium tetrametaphosphate**, $\text{Mg}_2\text{P}_4\text{O}_{12} \cdot 10\text{H}_2\text{O}$, are formed. 100 parts of water dissolve 1.43 parts of the salt. The hydrate is decomposed by acids, particularly conc. sulphuric acid. When calcined, the whole of the water is driven off, and the molten mass is glassy when rapidly cooled. According to H. Rose, an aq. soln. of hexametaphosphoric acid gives a precipitate of **magnesium hexametaphosphate**, when

added to a soln. of magnesium and ammonium chlorides. The precipitate is soluble in much water. T. Graham found that a gum-like precipitate is obtained when sodium hexametaphosphate is added to a soln. of magnesium acetate, but not to one of magnesium sulphate. H. Rose obtained no precipitate by adding aq. ammonia to a soln. of magnesium sulphate mixed with a sufficient quantity of sodium hexametaphosphate.

W. Gregory accidentally discovered what G. Tammann considers to be **sodium magnesium octometaphosphate**, $\text{Na}_2\text{Mg}_3\text{P}_8\text{O}_{24}$, in the preparation of phosphoric acid. In the extraction from bones by J. von Liebig's process, there is first a separation of magnesium metaphosphate, $\text{Mg}(\text{PO}_3)_2$, and then by repeated dilution and heating, the double octophosphate appears, which can be separated from the excess of phosphoric acid by treatment with cold water. G. Tammann obtained the double salt by melting a mol of a magnesium compound with a mol of tetrahydrated ammonium sodium hydrophosphate, and stirring the mass as it cools. The crystals are said to be rhombic dodecahedra, which, when dried at 100° , are free from water. According to W. Gregory, and R. Maddrell, the salt is insoluble in water or aq. phosphoric acid, soluble in conc. sulphuric acid, and slightly soluble in hydrochloric acid and aqua regia. G. Tammann said that the salt is insoluble in the two last-named menstrua; and that alkali sulphides have scarcely any action on the salt.

CHAPTER XXX

ZINC AND CADMIUM

§ 1. The History of Zinc and Cadmium

Gold and silver excepted, there is no metal which has had formerly so many and so wonderful names as zinc.—J. BECKMANN.

The history of zinc furnishes a remarkable example how slowly progress is made when observations are not interpreted by the scientific method, and when the fundamental laws concealed in a phenomenon have not been recognized.—F. X. M. ZIPPE.

THE mode of preparing *orichalcum* or *brass* from copper was known over 2000 years before the metal zinc was discovered, and it required a good many years' more observation before the alloying of the two metals, zinc and copper, was recognized as the essential process involved in the manufacture of brass. It is not surprising, said J. Beckmann,¹ that zinc should have remained so long unknown, for it had never been found in the metallic state. Its ores are often and in a great degree mixed with foreign ingredients; and when they are melted, the zinc sublimes in a metallic form, and is found adhering to the cool sides in the upper part of the furnace; but a particular apparatus is necessary, else the reduced metal partly volatilizes, and is partly oxidized, by which means it appears like an earth, and exhibits to the eye no traces of metal.

The term *brass* is mentioned several times by the biblical writers—nearly 4000 years B.C., for instance, we are told in *Genesis* (4. 32), that Tubalcain was a worker in brass and iron; and the brass or bronze looking-glasses of women are mentioned in *Exodus* (38. 8). There are also frequent references to brass or bronze in the early writings of Homer, about 1000 B.C., and of Hesiod, about 700 B.C. So far as we can gather, the early writers confused copper, brass, and bronze because the same term was employed for any or all these metals. The word rendered brass should be translated bronze. It is known that it was customary in very early times for women to wear a bronze mirror as an article of dress; M. H. Klaproth has analyzed one such, and found: copper, 62; tin, 32; and lead, 6 per cent.

In the work *ἐν Θαυμαστοῖς*—on marvels—wrongly attributed to Aristotle about 320 B.C., but more probably written about the middle of the third century, it is said that bronze without tin was made at Mossynœcia, near the Black Sea, by melting copper with a peculiar earth which was found in the neighbourhood. In the first century of our era, Dioscorides, in his *De materia medica*, and Pliny, in his *Naturalis historia* (34. 2), called the earth *καδμεία* or *cadmia*, and the latter, probably both, used the term for the flue-dust which collects in smelting furnaces. C. Salmasius said that Dioscorides meant a native earth rich in zinc; and J. Beckmann, that he meant furnace-calamine. The name is perhaps derived from Cadmos, the son of Agenor and Telephasse, who brought the *κάδμου τέχνη* from Phœnicia to Greece, and *καδμεία* may be analogous with Theban earth. According to E. O. von Lippmann,² the metal zinc is not mentioned in the Ebers' papyrus, nor was it known as a metal to Aristotle, Dioscorides, or Pliny. The metal is not mentioned by Marco Polo in his travels in Persia at the end of the thirteenth century, although he describes *tutia* or *totia*. The Arabians who translated the Greek writers speak of the preparation of brass, but they have nothing to say about the metal zinc.

It is probable that the alloy known as *orichalcum* or *brass*, *tombac*, *pinchbeck*,

etc., was first discovered by smelting cupriferous zinc ores which yielded not copper but brass. Mines that contained ores, from which the gold-coloured metal was produced, were held in the highest esteem, and the early brasses seem to have been obtained by the smelting of such ores from mines in Laurium (near Athens), Sardinia, and Cyprus.³ In course of time, it was observed, possibly by accident, that an earth, which was probably calamine, when added to molten copper gave it a yellow colour; and this as a method of preparation was found to be more convenient than procuring the brass from zinciferous copper ores. This is the method to which the pseudo-Aristotle above refers. According to E. von Bibra,⁴ the Greeks were not acquainted with the manufacture of brass, but that alloy was made about the time of Augustus, near the beginning of the Christian era, by heating copper with certain earths—presumably containing zinc, *e.g.* calamine, galmei, or tutty—mixed with carbon. Brass was thus known to the Romans; and about the eleventh century, the process of manufacture was described by the monk Theophilus.⁵ As the zinc was reduced, it alloyed with the copper by cementation, forming the golden-yellow colour characteristic of a low-zinc brass. It is remarkable that the same word *cadmia* should have been employed for both the zinciferous ore and the flue-dust—an impure zinc oxide—found in furnaces smelting zinciferous ores. According to J. Beckmann, the term *tutia*, employed by Avicenna in the eleventh century, seems to have been used in a similar manner. A work attributed to Zosimus of Panopolis stated that brass is made by melting Cyprian copper with *tutia*. In spite of this, the furnace-calamine, which collected about the furnaces at Rammelsberg, was rejected as useless until the middle of the sixteenth century, when E. Ebener, about 1548, discovered that it could be employed in making brass.

The alloy was termed orichalcum by the Romans, who obtained the word from the Greeks' ὀρείχαλκος = ὄρος, a mountain, and χαλκός, copper or bronze. The term *aurichalcum* is a mis-spelling⁶ due to the resemblance which *orichalcum* bears to *aurum* (gold); and the term *aurichalcum* reappears, still more corrupted, in the French *archal*. It has been suggested that the German term *Messing* for brass is a corrupt form of Mossynœcia⁷—*vide supra*. Both words, orichalcum and aurichalcum, were used for brass about the beginning of the Christian era, but they were probably also employed in some cases for bronze. Attempts have been made to derive the term *zinc* from the Persian *tscheng*, or the newer Persian *seng*.

According to Cicero,⁸ who wrote near the beginning of our era, Roman coins made from orichalcum were undistinguishable from gold, and he raised the ethical question whether an honest man should acquaint a person who was really selling *aurum* but thought he was selling *orichalcum*, or should he buy for a penny what was worth a thousand times as much? The only metal which the Romans could have so mistaken for gold is the alloy of copper and zinc now called brass. Several brass coins of the Roman period have been analyzed by J. Percy,⁹ W. Gowland, J. A. Phillips, F. Göbel, H. Garland, etc. A selection of these analyses by W. Gowland is indicated in Table I. Traces of nickel, antimony, and arsenic were reported

TABLE I.—ANALYSES OF ANCIENT BRASSES.

Brass.	Date.	Cu	Sn	Zn	Pb	Fe
Augustus coin	30 B.C. to 14 A.D.	87·05	0·72	11·80	tr.	0·43
Tiberius coin	41 A.D.	72·20	—	27·70	—	—

in the first and sixth alloys, and 0.20 per cent. of antimony and 0.24 per cent. of nickel in the third, and 0.10 per cent. of nickel in the last one. According to F. Göbel, zinc is found only in alloys of Roman origin. The bronze objects derived from the Greeks and their colonies in Italy, Egypt, Asia, etc., invariably consist of copper and tin, with or without lead.

Scholars have not been able to find in the works of any other classical author one single statement which would support the view that the Greeks or Romans were acquainted with the element zinc; but there are some reputed finds of the metal among ancient remains. According to G. F. C. Fuchs,¹⁰ the oldest piece of zinc extant is an idol found in a prehistoric Dacian settlement at Dordosch, Transylvania. It contained: zinc, 87.52; lead, 11.41; and iron, 1.07 per cent. According to P. C. Grignon, in 1772, a small metal bar of zinc was found in the ruins of an old Roman town at Champagne. He said that the bar had been worked to some extent, and added that in the neighbourhood of the town, there was an iron mine containing a great deal of zinc. A zinc relic has also been reported from the ruins of Pompeii (destroyed 79 A.D.); and M. Salzmann found in the ruins of Camiros (Isle of Rhodes), destroyed 500 B.C., a bracelet of silver inlaid with zinc. *Voici deux faits positifs*, said R. Jagnaux, *qui prouvent indubitablement que les anciens ont su extraire le zinc de ses minerais*; but J. Beckmann said that the first case had been examined only in a superficial manner; and there is nothing to show what kind of a metal or alloy P. C. Grignon considered to be zinc. K. B. Hofmann¹¹ questions the Pompeian find because a search for the fountain in the museum at Naples has not been successful. There is a hint in Strabo's *Geographia* (13. i, 56), written about 20 A.D., of a kind of mock-silver—*ψευδαργυρον*, or *pseudo-argyrum*—which furnished *orichalcum* when heated with copper. The ancient geographer said:

There is a stone near Andeira which becomes iron when it is burnt, and afterwards, when it is melted in a furnace with a certain earth, it drops mock-silver, which with the addition of copper, produces what is called . . . orichalcum. Mock-silver is also found in the neighbourhood of Tenolus.

The term *pseudoargyrum* or mock-silver must here have been intended to represent a metal with a certain resemblance to silver, but the only metals then known to have the colour of silver were mercury, lead, and tin; and the first two of these would not communicate to copper the properties ascribed to *orichalcum* nor does the description fit well with tin. It has therefore been conjectured that metallic zinc was known in the first century of our era. It is, however, unlikely that zinc would collect in drops like Strabo's *pseudoargyrum* unless it be assumed that the furnace was provided with a distillatory and condensing apparatus. J. Percy, however, does mention that occasionally the vapour of zinc may be accidentally condensed in cracks in the walls of furnaces, and trickle down in drops. M. Gsell assumed that Strabo's *pseudoargyrum* was metallic arsenic; F. X. M. Zippe, arsenical copper; and H. W. Schäfer, an arsenical alloy. In any case, P. Diegart and B. Neumann conclude that the *pseudoargyrum* was not metallic zinc.

According to A. J. C. Geerts,¹² the first Chinese book to mention *ya-yuen* (literally, lead of inferior quality) was called *Tien kong kai ou*, and it was published at the beginning of the seventeenth century; in that work, it is stated that the metal is mentioned only by the then modern writers, not the older ones. The Chinese encyclopædia *Pen tsao kang mu* appeared in the latter half of the sixteenth century, and it contains no reference to zinc, although it is said to have been compiled from the writings of some 800 authors. Calamine brass, however, is described. W. Hommel found a sample of Chinese zinc dated 1745 contained: zinc, 98.99; iron, 0.675; and antimony, 0.245 per cent., and no copper, nickel, silver, lead, or arsenic was present. B. G. Sage has written an account of the early use of zinc money in China.

The Hindu work *Rasarnava*, which appeared between the twelfth and the fourteenth centuries, mentions an essence of the appearance of tin which is obtained by

heating *rasaka* (calamine) with certain organic substances in a covered crucible ; and the fourteenth-century book *Rasaratnassamuchchaya* describes an apparatus for obtaining the essence of calamine by distillation—Fig. 1. The essence was not at first classed as a metal, but, according to P. C. Ray, in 1374, K. Madanapala called it *jasada*, and included it among the metals. The Hindus obtained but small quantities of zinc. The technical production and uses of this metal were first described in the Chinese book *Tien kong kai ou* of 1637. The Chinese encyclopædia *Wa kan sai dzu ye* of 1713, is said to refer to lead as *ya-yuen* and *totan*—from the Sanscrit *tuttham*, and the Persian *tutia*. Calamine is designated in Sanscrit *rasaka*, *kharpara*, and *tutthia*, and the last, when translated into Persian and Arabian, became *tutia*, so that zinc was called *ruh-i-tutia*, literally, the spirit of tutia. In Persia, *white tutia* was zinc sulphate ; *blue tutia*, copper sulphate ; and *green tutia*, ferrous sulphate. Just as in the sixteenth and seventeenth centuries, the term *counterfey* was applied to all kinds of metals and alloys—zinc, pewter, bismuth, antimonial lead, arsenical copper, etc.—so were the terms for zinc applied to all sorts of metals and alloys. Antimony, or antimonial lead, but not zinc, was described as *kharsini* by Kazwini, the Persian Pliny, in his *Cosmographia*, 1200 A.D. This subject has been discussed by A. I. S. de Sacy. From this it would appear that the art of zinc smelting originated in India, and was carried to China, where zinc was produced on a large scale until the middle of the eighteenth century. According to T. Bergman, zinc was brought to Europe from the East by the Portuguese a century before it was produced as a commercial article in Europe, excepting perhaps a small amount occasionally obtained as a by-product in the lead furnaces of Goslar.

FIG. 1.—Indian Apparatus for Extracting the Essence of Calamine by Distillation *per descensum*.

The alchemists of the Middle Ages, like the Romans, knew that when copper is heated with certain earths, a white arsenical or yellow zincic alloy is formed ; and effects of this kind were mentioned in the thirteenth century by Albertus Magnus, in his *De mineralibus et rebus metallicis*, as having been obtained by using what he called *marchasite aurea*. Hence, his golden marcasite was either arsenical or zinciferous pyrites—probably the former. Albertus Magnus, like Pliny, distinguished between *tutia* (furnace calamine) and *lapis calaminaris*, and stated that the former is an artificial product, the latter a mineral, and added that either of these substances imparts a golden colour to copper. He advised the use of glass-gall to be strewn over the molten metal, otherwise the *tutia* or *lapis calaminaris* will lose its force in the fire.

After Albertus Magnus there is a long interval stretching over three centuries during which little or nothing appears to have been written on the subject, but, added J. Beckmann, it was probably not forgotten by the alchemists :

On account of the great hopes which it gave the alchemists by its colouring copper, they described it purposely in an obscure manner, and concealed it under other names, so that it has not been recognized in their works.

There is, however, no evidence to show that zinc was recognized in Europe as a metal prior to the beginning of the sixteenth century, when Paracelsus employed the term *zinc* for the first time. In his incomplete tract *Liber mineralium*, published posthumously about 1570, Paracelsus wrote :

There is another metal, *zincum*, which is in general unknown to the fraternity. It is a distinct metal of a different origin, although adulterated with many other metals. It can be melted, for it consists of three fluid principles, but it is not malleable. In its colour, it is unlike all others, and does not grow in the same manner ; but with its *ultima materia* I am as yet unacquainted, for it is almost as strange in its properties as *argentum vivum*. It admits of no admixture, will not bear the fabrications of other metals, but keeps itself entirely to itself.

It may be doubted if Paracelsus understood by the term *zincum* what is understood to-day, since, in another essay, *On the element water*, he said that *zincum* is a bastard metal from copper, and that bismuth is a bastard metal from tin. He appears to have used the term *bastard metal* for impure separations—possibly calces—which he elsewhere called the *faces of the pure metals*.

In the sixteenth and seventeenth centuries there was much confusion as to the meaning of the term zinc, and it appears to have been employed locally by the miners of the Kärnthen district for an earthy ore, and generally, not for the metal, but for a number of different minerals. According to J. Mathesius,¹³

Counterfey is a metal of little value formed by additions and colouring substances, so that it resembles silver, as an image, or anything counterfeited, does its archetype. Thus, copper is coloured by calamine and other mixtures, in such a manner that it appears to be pure gold.

In his *De re metallica* (Basilæ, 1546), published before Paracelsus' tract, G. Agricola mentioned a white metal which he called *counterfei*, and which was found on the walls of a furnace smelting lead ores at Goslar in the Harz, and was probably recognized before Albertus Magnus' time. G. Agricola referred later to the formation of *zincum* in the furnaces of Silesia, but he does not appear to have correlated *counterfei* with *zincum*. This was done by G. E. von Lohneyss in 1690, who said that the metal zinc or *counterfey* greatly resembles tin, and remarked that the metal "zinc or bismuth" was in great demand by the alchemists. J. H. Pott, quoting from Jungius' *Mineralogia*, stated that towards the end of the sixteenth century the sale of zinc from Harz was prohibited by the ruling prince, who had a passion for alchemy, and who appears to have entertained high hopes of its utility in making gold. G. E. von Lohneyss also gave an account of the method of procuring zinc at Goslar. He said :

The metal *zinc* or *counterfeht* is formed under the smelting furnaces and in the crevices of the wall where the bricks are not well-plastered. When the wall is scraped, the metal falls down in a trough placed to receive it. . . . The metal is not much valued, and the workmen collect it only when they are promised *Trinkgld*.

A. Libavius used the Hindu term *caläem* for zinc, and in a letter expressed his regret that he had not been able to procure any of the metal; he seems to have regarded zinc as a peculiar kind of tin which took fire when heated in air. J. R. Glauber knew that the zinc brought from the East could be extracted from galmei, calamine, or tutia; and he said :

Zinc is a volatile mineral or half-ripe metal when it is extracted from its ores. It turns copper into brass as does *lapis calaminaris*, for indeed, this stone is nothing but infusible zinc, and zinc might be called a fusible *lapis calaminaris* inasmuch as both of them partake of the same nature . . . zinc sublimates itself into the cracks of the furnace whereupon the smelters frequently break it out.

P. M. de Respours¹⁴ used the term zinc in his work : *Sur l'esprit minéral*. About this time zinc seems to have been regarded as a compound of two or three elements.

Albertus Magnus supposed that iron is an ingredient of zinc; Paracelsus called zinc a spurious son of copper; N. Lemery believed it to be a kind of marcasite similar to bismuth; J. R. Glauber considered it to be immature solar sulphur; W. Homberg regarded it as a mixture of tin and iron; J. Kunckel called it a coagulated mercury; and F. de Lassone, and C. F. Wenzel seem to have considered phosphorus to be an essential constituent of zinc, probably because of the fact, observed by J. F. Henckel, that zinc calx phosphoresces when heated.

T. Bergman, in his dissertation *De mineris zinci* (Upsala, 1779), attributed the slow progress in the recognition of the individuality of zinc to the volatile and combustible nature of the metal. When zinciferous products are smelted with copper, the latter fixes the volatile zinc and produces brass. The first stage in the history of zinc is the recognition that a peculiar metal is fixed by copper when certain earths are smelted with that metal. Thus after nearly 2000 years, J. Kunckel

could say that calamine allows its metal part to pass into copper and form brass, and the same idea was advocated by G. E. Stahl. Even as late as 1735, G. Brandt considered that zinc could not be reduced to metal except in the presence of copper. According to W. Hommel, the name and the discovery of the metal have been erroneously ascribed to Basil Valentine; he attributed the demonstration that zinc is the metal of calamine to W. Homberg in 1695; while J. F. Henckel prepared zinc from calamine by heating it with some inflammable substance (phlogiston), but he concealed the method. A. von Swab (1742), and A. S. Marggraf (1746) proved that calamine could be reduced to the metal and distilled in closed vessels in the absence of copper.

The gradual recognition of zinc (i) as a constituent of calamine brass, and (ii) as a chemical individual by the European chemists, was virtually independent of the fact that the metal was brought to Europe by the East Indian traders under the name *tutenag*; *tutanego*, or *tuteneque*, and sold under the name *spialuter*, *spialter*, or *Indian tin*. Robert Boyle¹⁵ called it *speltrum*; the word was spelt in many different ways about that time, and these differences finally crystallized into *spelter*.

The term *spelter* is commonly used for ordinary commercial ingot zinc, whereas the term *zinc* is applied to the rolled metal. Latterly it is common to employ the term *spelter* for all grades of metal with up to about 99.8 per cent. of zinc; the grades of higher quality being termed *fine-zinc*. The crude zinc being obtained from the ores by smelting is termed *virgin spelter*, or *primary zinc*. Metal that has been remelted is called *remelted spelter*, or *secondary spelter*. The term *hard spelter* refers to a cheap brand of zinc contaminated with iron, a resultant of the galvanizing process.

Although zinc was well known in Europe towards the end of the seventeenth century, the extraction of zinc from its ores attained no industrial importance until early in the nineteenth century. The manufacturers of calamine brass by the cementation process were opposed to the preparation of brass by fusing copper with zinc because, they averred, it produced a brass of inferior quality. The art of zinc distillation, said G. Borgnet, was almost certainly introduced into Europe from the East in the early part of the eighteenth century. T. Bergman records a tradition that a few years prior to 1740, an Englishman went to China to study the smelting of zinc. According to R. Watson, and W. Pryce, Isaac Lawton was the first in England to establish a practical method for extracting zinc from calamine. About 1740, J. Champion established a works at Bristol for the extraction of zinc by distillation *per descensum*. In this process, a covered crucible, fitted with an exit tube leading from the bottom, was heated with the charge in one of the arches of a glass furnace; one furnace carried about half a dozen crucibles. As soon as zinc vapours began to appear at the mouth of the exit tube at the bottom of the crucible, a long condensing tube was attached. The zinc condensed in the tube and collected in suitable trays. Calamine, an important ore of zinc, had previously been used for making brass in various districts—Surrey (c. 1650), Bristol (1702), Cheadle (Staffs.) (1720), and later at Smethwick, Swansea, and Llanelli.

According to L. von Wiese,¹⁶ the Bristol process for the extraction of zinc from its ores was started at Wessola (Pless, Silesia), in 1798, by J. R. Ruhberg. An old glass furnace was utilized for the purpose. The works at Wessola were the beginning of the famous Silesian zinc industry. J. R. Ruhberg found that the Bristol process, distillation *per descensum*, was inefficient, and devised a process involving the use of muffles of large capacity. J. J. D. Dony, also, about 1805, started zinc distillation near Liège in Belgium. In 1809, he patented the *Konstruktion eines Ofens, um Zink aus Galmei zu gewinnen und das dazu angewandte Verfahren*. He used a series of small retorts set in a single furnace. The Belgian zinc industry soon became a formidable rival to the Silesian. B. Dillinger, at Dollach (Carinthia), also started distilling zinc from calamine about 1799, but the industry did not flourish here as it did in Silesia and Belgium. Both in Belgium and Silesia zinc was distilled *per ascensum*, and this process proved more economical than the distillation *per descensum* process. Britain

did not keep pace with the advances made in Upper Silesia, in Rhenish Prussia, and in Belgium. The primitive distillation furnaces remained in England until the middle of the nineteenth century, when Britain's lead in the zinc industry declined. It has been said that the failure of British metallurgists to keep pace in the art which they had introduced into Europe from the East, is one of the strange things in the history of metallurgy. Zinc smelting on a smaller scale was adopted in Austria, Spain, Holland, and in France about the middle of the nineteenth century. The regular manufacture of zinc in the United States was started about 1859 by J. Wharton.¹⁷ There has been no radical change in the metallurgy of zinc since the first Belgian furnaces were built in the early part of the nineteenth century.

The history of the discovery of cadmium is comparatively simple. It is a common companion of zinc. In the autumn of 1817, F. Stromeyer,¹⁸ of Göttingen, noticed that a sample of zinc carbonate from the zinc works at Salzgitter was tinged yellow although free from iron, while zinc carbonate from many other sources is white. He attributed the yellow coloration to the presence of a new element, and found indications of the same element in samples of zinc and zinc oxide from several other places. In May, 1818, K. S. L. Hermann, of Schönebeck, examined a sample of zinc which had been condemned because it gave a yellow precipitate, characteristic of arsenic, when an acid soln. was treated with hydrogen sulphide. He found that the yellow precipitate was not arsenic sulphide, but rather the yellow sulphide of a new element. Shortly afterwards, W. Meissner, of Halle, confirmed K. S. L. Hermann's discovery. C. J. B. Karsten, of Berlin, discovered the presence of the new element in the Silesian zinc ores, and he proposed to call the element *melinum*—from *melinus*, a quince—on account of the quince-like colour of the hydrogen sulphide precipitate; L. W. Gilbert proposed the term *junonium*, in honour of the discovery of the asteroid Juno, in 1804; and J. F. John proposed *klaprothium*, in honour of M. H. Klaproth; but F. Stromeyer's proposal *cadmium*—after *cadmia fornacum*, because the element accumulates in the flowers of zinc, which collects as fine-dust in zinc furnaces—was finally accepted. F. Stromeyer's element was thought by some to be identical with an element announced by K. S. L. Hermann, and called *vestium* or *vestalium*, but F. Stromeyer showed that the latter announcement was based on a mal-observation. C. H. Roloff has written on the history of cadmium.

§ 2. The Occurrence of Zinc and Cadmium

Zinc is a common element; cadmium is comparatively rare. F. W. Clarke¹ estimates that zinc is 200 times as abundant as cadmium. There are reports of the occurrence of small quantities of metallic zinc in the basaltic rocks of Brunswick (Victoria),² by L. Becker, and by T. L. Phipson. According to G. H. F. Ulrich, this zinc contains about one per cent. of cadmium. L. Becker also reported the occurrence of zinc, containing some cadmium, on the banks of the Mitta Mitta river, New South Wales. J. Park reported finding zinc near Hape Creek (Tharres, N.Z.);

W. D. Marks, in N.E. Alabama; and J. D. Dana, in Shasta Co., California. Zinc is present in small amounts in igneous rocks, and traces are also diffused in many sedimentary rocks. J. D. Robertson³ found the granite, porphyry, and diabase from Missouri contained 0.00139 to 0.0176 per cent. of zinc—average 0.009. Smaller proportions were present in the adjacent limestones, thus, the Silurian limestone contained 0.00016 to 0.01536 per cent. of zinc, and a trace up to 0.00255 per cent. in the lower carboniferous limestone; S. Calvin and H. F. Bain reported 0.00029 per cent. of zinc in the limestones and *dolomites* of Iowa; and A. M. Finlayson obtained results of the same order of magnitude for British rocks and more abundantly in the granites than in the limestones. H. Traube found 1.06 to 1.38 per cent. of zinc carbonate in the *aragonite* of Tarnowitz; and W. Biltz and E. Marcus found zinc and cadmium in the Merimian limestone of Coburg. L. Dieulafait tested hundreds of rocks and always found zinc to be present. F. W. Clarke and G. Steiger found the averages from hundreds of samples:

	Oceanic red clay.	Ferruginous oceanic clays.	Mississippi silt.	American igneous rocks.	Average.
NiO ₂	0.0320	0.0630	0.0170	0.00655	0.0296
As ₂ O ₅	0.0010	tr.	0.0004	0.00074	0.0050
PbO	0.0073	0.0004	0.0002	0.00081	0.0022
CuO	0.0200	0.0160	0.0043	0.01167	0.0130
ZnO	0.0052	0.0070	0.0010	0.00638	0.0049

Some zinciferous clays, called *tallow clays*, containing the eq. of 4 up to 56 per cent. of zinc oxide, occur in Missouri, Kansas, and Virginia.⁴ Zinc has been reported by E. Manasse,⁵ and H. Ungemach in *tetrahedrite*; by F. Mattonet and J. H. L. Vogt in *fahlerz*; by V. M. Goldschmidt, and C. Frenzel, in *argyrodite* of Bolivia; by A. de Gramont in *silver-glance*; and E. Manasse in *chrysocolla* of Campiglia. Zinc has also been reported in slags from lead and iron works by A. Stelzner, J. J. Porter, and H. Fettweis; and in blast furnace gases by E. Jensch, and A. Vita. O. Grass found cadmium in the flue-dust of a roasting furnace using Zwickau coal; and also in a lead furnace of Corphalie. P. Soltsien, and W. D. Harkins and R. E. Swain found zinc in the atm. about zinc smelters. A. Jorissen and E. Prost found zinc in the soils of Lüttich, and A. Jorissen, and P. Soltsien noted the transport of zinc from the soil to buried corpses in the cemeteries. L. Dieulafait also found zinc in the drainage from many soils. Zinc was found in the volcanic products at Soma (Vesuvius) by A. Scacchi; and by E. Casoria in the sublimation products of Vesuvius. Spectroscopic observations led J. N. Lockyer,⁶ and M. N. Saha, C. A. Young, C. C. Hutchins and E. S. Holden, A. C. Jones, and H. Kayser and C. Runge to infer that zinc and cadmium are present in the sun.

The ores of zinc are widely distributed, and they are common in mines furnishing various base metals, and more particularly they are found associated with the ores of lead, silver, and copper.⁷ Most of the old calamine (zinc carbonate) mines are exhausted, and more complex ores have now to be treated for zinc. The more important deposits of zinc—illustrated by the chart, Fig. 2—contain ores so complex that they present rather difficult problems to the metallurgist.

Zinc ores occur and have been mined in many parts of **Europe**—for instance, in the United Kingdom in Cumberland, Isle of Man, Flintshire, Cardiganshire, Dumfriesshire, Lanarkshire, Shropshire, and elsewhere. Germany ranks as a second largest producer, after the United States. The most important deposits are in Upper Silesia, while smaller deposits occur in Rhineland, Westphalia, Nassau, Harz, etc. In Greece, the Laurium mines are of great antiquity; in Italy, the Sardinian mines are unusually rich, and there are also deposits in Lombardy, Piedmont, and Tuscany. Most of the zinc ore mined in Spain comes from Murcia and Santander, while smaller amounts come from Teruel. The Ammeberg mines in Nerike, Sweden, are important, and deposits also occur in Orebro and Kopparberg districts. In Norway, deposits occur at Haderland, Sadon, and Primorsk. The more important deposits in France are at Malines (Gard), Pierreflitte (Hautes Pyrenées), Bulard de Santein, St. Lary (Ariège), Planisles (Lot), Bleybard (Lozière) and Bormettes (Var). The chief deposits in Belgium are at Bleyberg, Vieille Montagne, and Moresnet; those at Welkenrodt, Nouvelle, Montagne, Corphalie, and Philippeville are the most important. The more important deposits in the old Austria-Hungary, in South Carinthia, Styria, and Tyrol. In

Asia, deposits occur in India at Bawdwin, Mohocheng, Udepur, and Sirmur; in the Hunan province in China; at Kamioka (Hida), Uzen, Tsuchima, Etchu, Echizen, and Bizen in Japan; Ridder Mine (Altai Mountain) in Siberia; at Trang, Tonkin, Than Mai, Yen Liuh, Brizard in Indo-China. In Africa, there are deposits at Hammam N'Bails, Ain Arko, Sakamody, Guerraouma, and R'Arbu in Algeria; Sidi-Ahmet, Fedj-el-Adoum, Zaghoun, and El-Akhout in Tunis; at Gebel Rosas in Egypt; and in Nigeria, Rhodesia, and the Transvaal. The United States of America is the largest producer of

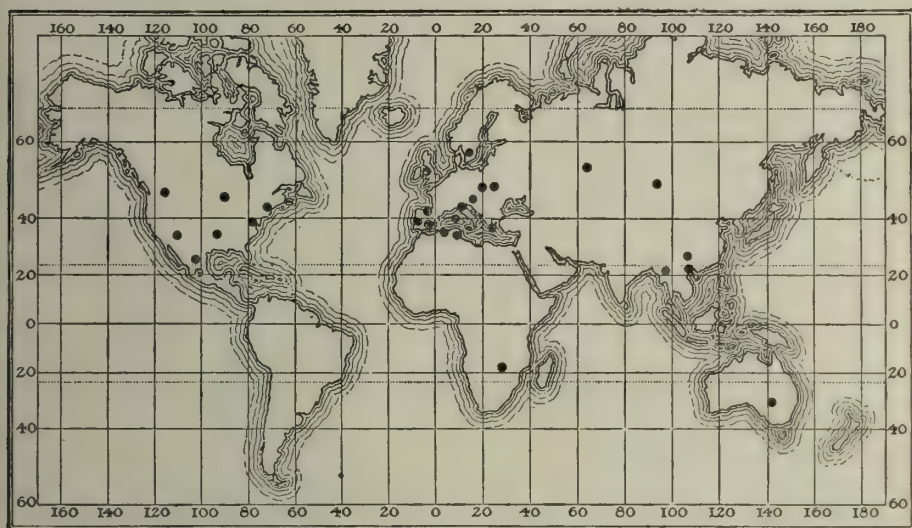

FIG. 2.—Geographical Distribution of the Chief Deposits of Zinc Ores.

zinc and spelter, and important deposits occur in Missouri, Colorado, Montana, Wisconsin, New Jersey, Idaho, Kansas, Utah, Oklahoma, Nevada, Arizona, New Mexico, Tennessee; In Canada there are deposits in British Columbia, Ontario, Nova Scotia, and Newfoundland. In Huanchaca in Bolivia; and at Chahuila, Chihuahua, San Luis Potosi, Tamaulipas, and Nuevo Leon in Mexico. There is a most important deposit of zinc and lead ores in the Broken Hill district of New South Wales, and at Mount Black and Mount Read in Tasmania, Australasia; Burketown in Queensland; and at Collingwood, Thames district, in New Zealand.

The World's production of zinc (spelter) is estimated in English tons (2240 lbs.) as:

1845	1855	1865	1875	1885	1895	1905	1913	1919
29,000	70,000	98,000	166,000	294,000	406,000	643,906	985,142	602,581

The output of spelter in metric tons (1000 kgrms.=2204.6 lbs.) for 1913 was:

U.S. America.	Germany.	Belgium.	France and Spain.	Great Britain.	Holland.	Austria and Italy.
320,283	283,113	197,703	71,023	59,146	24,323	21,707

with Norway, 9287; Russia, 7610; and Australia, 3724 metric tons. This distribution of the World's production⁸ is almost certain to be considerably altered when the markets are in a state of equilibrium after the disturbances due to the Great War. The highest and lowest prices of commercial zinc per ton were:

	1900	1905	1910	1912	1914	1915	1920
Lowest .	£18 10s.	£23 5s. 0d.	£21 12s. 6d.	£25 0s. 0d.	£21 6s. 3d.	£28	£22½
Highest .	£22 15s.	£29 2s. 6d.	£24 5s. 0d.	£27 12s. 6d.	£34 0s. 0d.	£120	£62½

The principal ores of zinc treated commercially are: zinc sulphide, zinc blende, or, as it is called in the United States, **sphalerite**. This ore is fairly widely distributed, and is associated with more or less galena, iron pyrites, cadmium and manganese sulphides, as well as magnetite, hematite, silver, etc., and occasionally small traces of indium, gallium, thallium, and gold. While the pure zinc sulphide, ZnS, contains 67.15 per cent. of the metal in the ideal case, the blende which is treated by the smelter has between 35 and

55 per cent. of metal. The residues, after the zinc has been separated, can often be profitably worked for lead and silver. Zinc blende is usually black or brown in colour, and the miners in some districts then call the mineral *black jack*; if the blende is yellow, it is sometimes called *resin blende*; white, red, or green blende is not common. A curvilaminar variety is called *Schalenblende*; a reniform variety, *Leberblende*, and there are also varieties *Blätterblende*, *Faserblende*, *Strahlblende*, etc. It sometimes occurs crystallized in the cubic system. A variety of zinc blende with over 10 per cent. of ferrous sulphide, and may be up to the eq. of $\text{FeS} \cdot 2\text{ZnS}$, is called *marmatite* from Marmato; and a fibrous form of zinc blende, called *wurtzite*, crystallizes in the hexagonal system. An oxysulphide, approximately $\text{ZnO} \cdot 4\text{ZnS}$, of little more than mineralogical interest, is called *voltzine* or *voltzite*.

Zinc carbonate, *zinc spar*, or *calamine*, or, as it is called in America, *smithsonite*; and in Germany, *Galmei*, was one of the earliest ores to be worked for zinc. The miners in some districts call this ore *dry bone*. In the ideal case, zinc carbonate, ZnCO_3 , contains 52 per cent. of metal but ores with as little as 13 per cent. of zinc are said to have been worked in Silesia. The impurities are mainly silica, lime, and iron, cadmium, and manganese carbonates. The mineral is white, or grey, tinged green or brown. It generally occurs massive with an imperfectly conchoidal fracture and vitreous lustre. Rhombohedral crystals are comparatively rare. A variety with over 20 per cent. of iron carbonate is called *monheimite*. The basic carbonate—*zinconise*, *zinc bloom*, or *hydrozincite*, $\text{ZnCO}_3 \cdot 2\text{Zn}(\text{OH})_2$ —contains about 57 per cent. of metal; it is white or yellow in colour, and usually occurs massive. A variety with copper carbonate is called *green calamine* or *aurichalcite*.

Thermochemistry throws some light on the occurrence of certain calcium, magnesium, and zinciferous minerals. The sum of the heats of formation of zinc sulphate and calcium carbonate is greater than of zinc carbonate and calcium sulphate; the formation of zinc carbonate and magnesium sulphate is accompanied by the evolution of more heat than zinc sulphate and magnesium carbonate. Hence, other things being equal, zinc sulphate is more likely to be found in limestone rocks and zinc carbonate in dolomitic or magnesian rocks.

Zinc silicate, Zn_2SiO_4 , or $2\text{ZnO} \cdot \text{SiO}_2$, is called *willemitite*, and in the ideal case, it has the eq. of 58.1 per cent. of metal, but the presence of manganese and iron lowers the proportion considerably. A flesh-coloured variety with 5 to 12 per cent. of manganese is called *troosite*. The silicate is reduced to the metal by heating it with carbon. The mineralogist's name *calamine*⁹ has been applied to both the carbonate and silicate, and some confusion has in consequence resulted. It has been argued that the term *calamine* is derived from the Hindu *calaēm*, which is related to the Arabic word *climia* or *calimia* used for what is called calamine.¹⁰ Willemitite is yellow or brown in colour. The hexagonal crystals have a sp. gr. 3.9 to 4.2; hardness, 5 to 5.5. The hydrated silicate, *hemimorphite*, *electric calamine*, or, in the States, simply *calamine*, $\text{Zn}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$, contains in the ideal case 53.7 per cent. of metal. This ore is not nearly so widely distributed as the sulphide or carbonate. The deposits in Aix-la-Chapelle and Moersnet (Belgium) are virtually exhausted, but there are extensive deposits in Virginia and Missouri. The Virginian deposits furnish a high-grade metal when treated by the distillation process of extraction. This mineral occurs massive with a subconchoidal fracture, or in rhombohedral crystals. The colour is white or yellowish-brown, and it sometimes has a green or blue tinge.

Native zinc oxide, *red zinc ore*, or *zincite*, ZnO , contains in the ideal case 80.2 per cent. of metal. It usually occurs massive; hexagonal crystals are rare. The colour is deep red, but if the ore occurs in thin scales, it is yellow by transmitted light. *Franklinite* is a kind of mangano-zinc ferrite, $\text{R}''\text{O} \cdot \text{R}_2'''\text{O}_3$, or $\text{R}_2''(\text{R}'''\text{O}_2)_2$, where R'' represents Zn , Fe'' , or Mn'' , and R''' represents Fe''' or Mn''' . Franklinite contains from 12 to 18 per cent. of zinc. It occurs in greyish-black octahedral (cubic) crystals. Workable deposits of franklinite and zincite are almost exclusively confined to the New Jersey district (U.S.A.). Franklinite is usually treated for zinc oxide, not for the metal.

In addition to these ores, there are other minerals of less importance—for instance, the anhydrous sulphate, *zincosite*, ZnSO_4 ; the hydrated sulphate *goslarite*, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, occurs in rhombohedral crystals; the aluminate, or *gahnite*, or *zinc spinel*, $\text{ZnO} \cdot \text{Al}_2\text{O}_3$, in cubic crystals; the arsenate, $\text{Zn}_3(\text{AsO}_4)_2 \cdot \text{Zn}(\text{OH})_2$, or *adamite* in rhombic crystals; *hopeite* is a hydrated zinc phosphate; etc.

Most zinc ores contain some cadmium, and in the extraction of zinc the cadmium accumulates in the flue-dust of the zinc furnaces. Small quantities of cadmium almost invariably accompany calamine and zinc blende. The highest value 3.4 per cent. was reported by R. Biewend¹¹ in the zinc blende of Eaton (U.S.A.); F. L. Bartlett found cadmium in the zinc blende from Leadville. F. Stromeyer found 2 to 3 per cent. in the blende of Przibram. C. Frenzel reported 1.136 per cent. in the blende of Nuissière; A. Damour, 0.13 to 0.21 per cent. in the zinc blende of Belgium; and E. Jensch, between 0.04 and 0.30 per cent., or on the average 0.102 per cent. of cadmium in the blende of Upper Silesia. According to E. Jensch, the

highest quantity observed in the zinc blendes of Hartz, Saxony, Bohemia, Hungary, Sweden, and Norway is 0.4 per cent. Cd. C. Rimatori found up to 1.66 per cent. of cadmium in 15 samples of zinc blende from Sardinia; E. D. Clarke found cadmium in the zinc silicates of Freiburg and of Derbyshire; in the zinc carbonate of Mendip, Derbyshire, and Cumberland, but not in specimens from Holywell, or from Hungary. A. Schmidt, and J. R. Blum found 1.58 per cent. of cadmium in calamine from Wiesloch; R. Bunsen reported cadmium in zinc sulphate from Hartz.

Cadmium occurs as **greenockite**, cadmium sulphide, CdS, usually as a bright yellow powder on zinc blende; hexagonal crystals are rare. The Arkansas and Missouri smithsonites are sometimes coloured with greenockite; a cadmiferous zinc blende with up to 5 per cent. of cadmium and with a reddish colour is called **przibramite**. The basic carbonate **otavite** has 61.5 per cent. Cd, according to O. Schneider; and the crystallized oxides are rare minerals.

W. F. Hillebrand¹² reported 0.10 per cent. of cadmium and 22.31 per cent. of zinc in the water of a spring on Shoal Creek (Missouri) and 0.37 per cent. of zinc in the water from Mountain view mine, Butte (Montana); C. P. Williams reported 0.02 and 0.09 per cent. of cadmium and 10.74 and 24.80 per cent. of zinc in two mine waters from the Missouri zinc region; M. Gläser and W. Kalmann, 0.06 per cent. of zinc in the water from Roncigno (Tyrol); and E. Ludwig, 0.30 per cent. of zinc in a spring water at Srebrenica (Bosnia). Several analyses of mine waters have been compiled by F. W. Clarke. G. Massol reported the presence of zinc in separations from the thermal waters at Uriage (Isère); and F. Henrich in the sinter from the Alder spring at Wiesbaden. The presence of zinc in sea-water was reported by L. Dieulafoy—0.0016–0.0020 grm. per cubic metre in the waters of the Mediterranean. A. Goldberg found zinc oxide in a boiler deposit.

The ashes of plants¹³ grown on zinciferous soils have been reported as containing up to 30 per cent. of zinc oxide. M. Javillier, and T. Richardson reported the presence of zinc and cadmium oxides in coal ash—e.g. the ash of coal from Berwick (Scotland) contained 2.03 per cent. ZnO, and 1.42 per cent. CdO. E. Jensch found 0.0033 per cent. of cadmium in the ash of a coal from Upper Silesia; G. Benz found zinc in fruit juices, and R. Bodmer, in wine; P. Soltsien found 0.0067 per cent. in apple syrup. D. Spence found zinc in indiarubber. H. Claassen found zinc in the boiler deposit of a sugar works; and G. Lechartier and F. Bellamy,¹⁴ in several plants, e.g. in barley, maize, wheat, beans, vetches, clover, beet-root, etc. According to G. Lechartier and F. Bellamy, and F. Raoult and H. Breton, the human liver may contain normally 10–76 mgrms. of zinc per kgrm., and L. van Itallie and J. J. van Eck found 17 to 79.6 mgrms. per kgrm. H. Matzkewitsch said that normally zinc is not present in the healthy organism. G. Lechartier and F. Bellamy also reported zinc in calves' liver, ox flesh, hens' eggs, etc. C. B. Mendel and H. C. Bradley also reported zinc to be a normal constituent of the liver of the sycotypus (mollusc) and found 15 per cent. in the total ash, and 1.2 per cent. in the dry tissue. V. Birckner found that baker's yeast, wheat, oats, corn, barley, rye, and rice contained 15 to 415 mgrms. Zn per 1000 grms. of fresh substance; ordinary market milk, 4.2 mgrms. per 1000 grms.; and human milk, 6 to 14 mgrms. About 0.005 per cent. of zinc occurred in the yolk of hens' eggs, and virtually none in the white part. From its constant occurrence in cows' and human milk it is inferred that this element exerts an important nutritive function which has not been yet discovered. R. S. Hiltner and H. J. Wichmann found zinc to be universally present in oysters of the Atlantic waters to the extent of 0.0260 to 1.300 grms. of zinc per kgrm.—average 0.457 grm.

§ 3. The Extraction of Zinc

The peculiar physical and chemical properties of zinc render the extraction of the metal from its ores somewhat costly, but the process is satisfactorily remunerative with high-grade ores containing a relatively large proportion of the metal.¹ Hence, low-grade ores are enriched by a preliminary process of conc. to remove gangue or worthless material, leaving about 50 per cent. zinc, before they are smelted.

Dry process of zinc extraction.—The operations involved in the dry process of extraction are, (i) the roasting or calcination of the ores; and (ii) the reduction of the roasted ores in a distillation furnace, by carbon at a temp. above the b.p. of zinc, 940°.

1. *The roasting of zinc ores.*—Calamine is roasted so as to drive off the carbon dioxide and water, and leave behind zinc oxide; hemimorphite may be calcined to drive off the combined water and leave zinc silicate behind; and zinc blende may be roasted to convert it into the oxide, and at the same time drive off as much antimony and arsenic as possible: $2\text{ZnS} + 3\text{O}_2 = 2\text{ZnO} + 2\text{SO}_2$. If the roasting of the blende is conducted at a low temp., a comparatively large amount of zinc sulphate is formed: $4\text{ZnS} + 7\text{O}_2 = 2\text{ZnO} + 2\text{ZnSO}_4 + 2\text{SO}_2$; at a higher temp. most of the sulphate is decomposed, forming the oxide: $2\text{ZnSO}_4 = 2\text{ZnO} + 2\text{SO}_2 + \text{O}_2$. It is necessary to convert the sulphide to the oxide because if converted to the sulphate, the latter would be reduced to the sulphide by the carbon in the distillation retort, and the sulphide is not reduced to the metal to any appreciable extent. The roasted ore contains about one per cent. of sulphur. The relative proportions of sulphide, sulphate, and oxide in a sample of roasting blende removed from the calcination furnace at four different stages in the operation, are, according to C. Schnabel:

	Beginning.	I.	II.	III.	IV.	End
Zinc sulphide . .	83	70.5	51.5	23.2	8.6	1.9
Zinc sulphate . .	0	3.7	4.2	12.3	6.2	5.9
Zinc oxide . .	0	15.2	38.0	57.8	75.5	81.0

A large variety of roasting furnaces of the reverberatory type are employed in which the charge is agitated mechanically or by hand. In the better class of installation, the sulphurous gases from the roasting blende are used for the manufacture of sulphuric acid.²

2. *The reduction and distillation of the metal.*—The volatility of zinc at bright red heat, enables the metal to be extracted from the ore by distillation processes. The powdered oxide is mixed with about half its weight of anthracite coal, i.e. a quantity four or five times in excess of theoretical requirements: $\text{ZnO} + \text{C} \rightarrow \text{Zn} + \text{CO}$, and heated in closed fireclay retorts to which condensers are attached. The retort is heated to 1200°–1300°. The heat has to pass through the walls of the retort, which are poor heat conductors. The retorts are accordingly made comparatively small. The zinc oxide is reduced by the carbon or carbon monoxide at a temp. higher than the b.p. of the metal. In consequence, as soon as the metallic zinc is reduced, it is vaporized and the vapour is condensed to a liquid in fireclay, or iron receivers or condensers adapted to the retorts. Carbon monoxide escapes. Zinc silicate ores—willemitte and hemimorphite—are also reduced by carbon, but at a higher temp. than is required for the oxide. There are some interesting phenomena associated with the process.

The vapour of zinc must be condensed at a temp. well under the b.p. and over the m.p. of the metal. When the zinc vapour is condensed below about 415°, it forms a powder—called *zinc dust*, *blue powder*, *zinc fume*, or *poussière*³ which is usually a mixture of 8 to 10 per cent. of zinc oxide with metallic zinc; if the temp. of the receiver exceeds 550° the vapour does not condense at all. Consequently, the permitted range for the temp. of the condenser is comparatively narrow—according to L. V. T. Lynen, 415° to 550°.

The reduction of the oxide to the metal is difficult. Assuming that the heat of formation of zinc oxide is 86 Cals.; of carbon monoxide, 29 Cals.; and of carbon

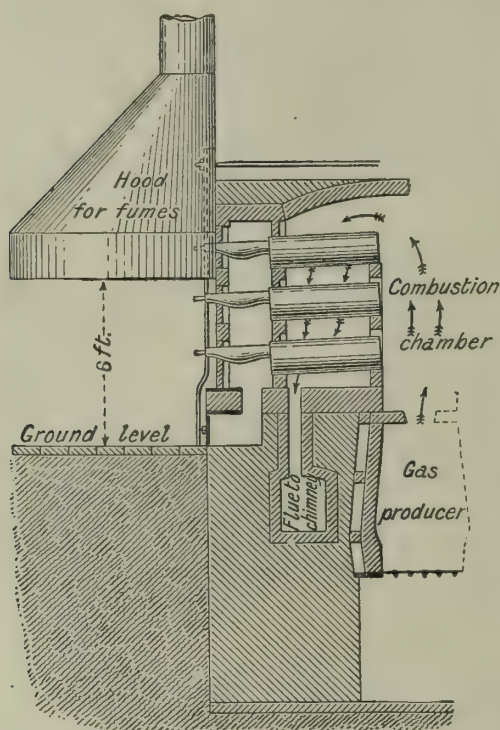

FIG. 3.—Transverse Section of half a Rhenish Zinc 3-tier Furnace.

The latter also found the temp. of calcination of the zinc oxide affects the temp. of reduction. Thus, zinc oxide calcined at 1100° and at 1300° is reduced by soft coke at 1048° and 1061° respectively. M. Bodenstein and F. Schubart found for the equilibrium constant, K , in the reaction: $\text{ZnO} + \text{C} = \text{Zn}_{\text{vapour}} + \text{CO}$, when p_1

dioxide, 97 Cals.; it follows by Hess' law that $\text{ZnO} + \text{C} = \text{CO} + \text{Zn} - 57$ Cals. M. Bodenstein and F. Schubart⁴ gave 89.6 Cals.; $2\text{ZnO} + \text{C} = 2\text{Zn} + \text{CO}_2 - 75$ Cals.; M. Bodenstein and F. Schubart gave $2\text{ZnO} + \text{C} = 2\text{Zn}_{\text{vapour}} + \text{CO}_2 - 141.9$ Cals. at 1000° ; and $\text{CO}_2 + \text{C} = 2\text{CO} - 39$ Cals.; and $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2 - 19$ Cals. This means that in the reduction of zinc oxide by carbon, the heat absorbed is 57 Cals., when the products of the reaction are taken to be cold; otherwise, an allowance must be made for the change in the sp. ht. of the different substances concerned in the reaction.

Although the reduction of zinc oxide by carbon can be detected below 700° , the reaction is so slow that temp. in the vicinity of 1300° are actually employed. M. Bodenstein and F. Schubart measured the temp. at which a mixture of zinc oxide and carbon is converted into zinc vapour and carbon monoxide at 28 mm., 87 mm., 266 mm., and 760 mm. press. The approximate temp. is 1030° in agreement with 1022° , by W. McA. Johnson.

FIG. 4.—Three Types of Zinc Retort.

and p_2 respectively denote the partial press. of zinc vapour and carbon monoxide, $K = p_1 p_2$, F. Schubart found

	596°	627°	665°	695°	729°	756°	795° C.
p_1	2.3	5.15	12.45	27.7	60	92	156
p_2	2.3	5.15	12.45	27.7	100	295	1097
K	1.8×10^{-9}	8.4×10^{-9}	4.5×10^{-8}	2.5×10^{-7}	1.5×10^{-6}	6.6×10^{-6}	3.9×10^{-5}
Q Cals.	—	-77	-74	-92	-112	-110	-98

where Q denotes the heat of the reaction. The temp. of the reaction is 921° when the press. is 28 mm.; 945° when 86 mm.; 982° when 266 mm.; and 1010° when 760 mm. The thermal value Q of the reduction of zinc oxide by carbon, calculated from the equation $\log K_2 - \log K_1 = -4.571Q(T_1^{-1} - T_2^{-1})$, between 1012° and 982° is -219.3 Cals.; between 982° and 946° , -185.6 Cals.; between 946° and 908° , -151.3 Cals.; and at ordinary temp., -89.6 Cals. At 1000° , $K=63$. It is also estimated that $\log_{10} Kp = -0.2188 \times 89600T^{-1} + 1.75 \times 2 \log_{10} T + 6$, approximately. An exact calculation was not made because of the want of knowledge of the equilibrium between carbon, carbon monoxide, and carbon dioxide with sufficient accuracy. M. Lemarchands showed that in an atm. of nitrogen, zinc oxide is readily reduced directly by carbon without the necessary intermediate formation of carbon monoxide. The amount of carbon entering into the reaction is intermediate between the amounts necessary for the two possible actions. $\text{ZnO} + \text{C} = \text{Zn} + \text{CO}$, $2\text{ZnO} + \text{C} = 2\text{Zn} + \text{CO}_2$. This is explained on the grounds that the reduction of zinc oxide by carbon monoxide, $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2$, takes place with a velocity superior to that of the reduction of carbon dioxide by carbon. This is possible, since the first action commences at 350° , and the second only at 400° . According to E. Jänecke, if solid zinc oxide and carbon be added to molten zinc in a space from which the air has been exhausted, then, at temp. above the m.p. of zinc, an equilibrium will be established between the two solid phases and one liquid phase and one gaseous phase. It is a univariant equilibrium, since the four phases may be formed from three independent components, and hence the press. and composition of the gas will be constant at a definite temp. and will vary with the temp.

In the reduction of the common metal oxides by carbon monoxide, the reaction: $\text{MO} + \text{CO} \rightleftharpoons \text{CO}_2 + \text{M}$, is reversible, but the conc. of the carbon dioxide must be very great before the back-reaction—reduction of carbon dioxide and oxidation of the metal—sets in with an appreciable velocity; but with zinc vapour, the back-reaction with carbon dioxide: $\text{Zn} + \text{CO}_2 \rightleftharpoons \text{CO} + \text{ZnO}$, occurs with a comparatively small conc. of carbon dioxide. Zinc vapour can be oxidized by carbon dioxide so that an excess of carbon must be present in the retort to maintain an atm. of carbon monoxide and keep the conc. of carbon dioxide very small by the reaction $\text{C} + \text{CO}_2 = 2\text{CO}$. According to O. Boudouard, carbon monoxide at 1000° acts as a reducing agent until about 0.1 per cent. of carbon dioxide is present and the system $\text{ZnO} + \text{CO} \rightleftharpoons \text{Zn} + \text{CO}_2$ is in equilibrium; any further proportion of carbon dioxide means that the back-reaction—oxidation of zinc—will occur. At 1125° , the equilibrium proportion of carbon dioxide is 0.2 per cent., and at 1500° , 0.76 per cent. The mean of seven analyses of the gases issuing from zinc retorts during distillation is: Carbon dioxide, 0.54 per cent.; carbon monoxide, 96.02; hydrogen, 2.56; and nitrogen, 0.74 per cent.

If the vapour of zinc be too much diluted with other gases, it can condense only to zinc fume, and not into fluid metal. The greater the proportion of these gases the greater the proportion of zinc fume. This fact, and the back reaction, indicated above, explains why all attempts to reduce the oxide in reverberatory and blast furnaces have not been satisfactory. Either zinc oxide or the troublesome zinc fume is obtained.

Three types of retort-furnace are used—the Belgian, the Silesian, and the so-called Rhenish, which is really a modification of the two former, and is perhaps the favourite type. Half a transverse section of a Rhenish furnace is shown in Fig. 3. It is supposed to be fired by gas made in a central gas producer. Each retort, with all three types, has three parts: the body, the condenser, and the prolong or nozzle. The smallest retorts are used with the richest ores, and conversely. There is, however, a considerable variation in the shape and size of the retorts used by different smelters, as is also the case with the arrangement of the retorts in the furnace. In the Silesian process, the typical retorts are comparatively large, Fig. 4, and might be termed muffles rather than retorts. There was only one tier of retorts in the original Silesian furnaces, but two and even three tiers may be used in a modern bank of retorts. The Belgian retorts are usually elliptical, rarely cylindrical, Fig. 4, and they are arranged in three to five tiers each containing 6 to 8 retorts.

The mode of arrangement is illustrated in Fig. 3. The Rhenish retorts are rather larger than the Belgian, and smaller than the Silesian, Fig. 4, and they are arranged in two or three tiers in double furnaces with 60 to 100 retorts on each side, Fig. 3. Some of the larger modern furnaces have over 1000 retorts. The furnaces are usually gas fired with or without regeneration; sometimes they are coal fired.

In the typical process, the retorts are recharged every 24 hrs. The retorts are cleaned and patched, or new retorts are substituted for defective ones. In some works special machines are employed for discharging the retorts. The well-mixed charge, slightly damped, is introduced by hand scoops. The condensers are luted on, and when the flames of the carbon monoxide burning at the mouths of the condensers are tinged bluish-green by zinc, the prolongs are fitted on, and the temp. of the retorts gradually raised. Molten zinc accumulates in the condensers, and zinc fume in the prolongs. The liquid zinc in the condensers is drawn off in the hand or other ladles from time to time. The appearance of the carbon monoxide flame burning at the exit tells the operator when the distillation is finishing. When completed, the spent residues are removed, and the cycle begins anew. The progress of the distillation can be observed through the open condensers of the Belgian and Rhenish systems. The whole cycle of operations occupies about 24 hrs. of which 19 hrs. are taken up by the distillation.

As previously indicated, the term *spelter* is applied in commerce either to all ingot zinc, or to a metal containing up to about 99.8 per cent. of zinc. If the metal contains over this amount of zinc, it is called *fine zinc*. The term *zinc* is usually reserved for the rolled metal, and for use in chemical and mineralogical nomenclature. Commercial spelter contains from 0.06 to 2.55 per cent. of lead; 0.01 to 0.26 per cent. of iron; 0.005 to 0.09 per cent. of cadmium; and up to 0.07 per cent. of tin.⁵ The lead is derived from the ores, and it distils over with zinc. The amount of lead in zinc cannot be reduced much below 0.2 per cent. by distillation; there appears to be a constant boiling mixture formed as in the case of aq. soln. of hydrochloric acid, etc. Good spelter should not contain over 1.5 per cent. of lead. The iron in spelter does not come from the ores, but is taken up when zinc is remelted in iron vessels, or stirred with iron rods. The presence of iron reduces the malleability of the metal. Good spelter does not contain more than 0.05 per cent. of iron. Probably all zinc contains some cadmium, and this element is not considered particularly deleterious, but it makes the metal more brittle, and when used for galvanizing, the presence of cadmium makes the coating more liable to peel off—this is serious on telephone and telegraph wires when the sharp bends make the coating crack or peel, exposing the underlying metal. It is derived from the ores, and distils over with the zinc. Traces of arsenic are usually present. Eight samples of Belgian, Silesian, Rhenish, and American spelters contained from 0.002 to 0.060 per cent. of arsenic; up to 0.02 per cent. of antimony; from 0.001 to 0.070 per cent. of sulphur; from 0.001 to 0.178 per cent. of carbon;⁶ from 0.002 to 0.137 per cent. of silica; from 0.0002 to 0.112 per cent. of copper; and in some cases slight traces of bismuth.

Many studies and modifications of the carbon reduction and distillation processes have been made.⁷ Other reducing agents have been suggested—W. E. Blass⁸ used carbon monoxide; H. Goldschmidt, aluminium; A. G. Betts, silicon or a silicide, alloys of aluminium, calcium, or magnesium, or a carbide; L. M. Bullier, E. W. von Siemens and J. G. Halske, and O. Frölich, calcium carbide. Instead of producing zinc directly, processes have also been devised for recovering zinc from alloys with other metals—lead, nickel, etc.—and also from slags.⁹

The blast furnace treatment of zinc ores.—Many attempts have been made to dispense with the large number of retorts employed in the ordinary distillation process, and to make the smelting a continuous process. E. F. J. Duclos¹⁰ and F. L. Clerc proposed the use of a closed blast furnace with a hot blast, and a condensing apparatus. The latter emphasized the importance of keeping the zinc vapours diluted as little as possible with carbon dioxide, and of not cooling the

vapour below the m.p. of the metal so as to avoid the formation of blue powder. E. E. Lungwitz proposed to smelt zinc ores in a blast furnace worked under a press. of about 120 lbs. per sq. in. with the idea of raising the b.p. of the metal. O. Nagel also worked a mixture of the zinc ore with coal in a blast furnace maintained full of water gas supplied through tuyères. Spelter was successfully produced, but the losses due to the formation of too large a proportion of blue powder and zinc oxide seriously hampered the processes.

The electrical smelting of zinc ores.—C. G. P. de Laval¹¹ introduced the electric smelting of zinc ores in Scandinavia, about 1904. The ore of zinc may be mixed with carbon, and charged into an electric furnace in such a manner as to form on its bottom a pile or stack sloping by gravity opposite to a source of electric heat. The pile of ore is continuous into the shaft into which the ore is charged. As the ore melts on its sloping face, it flows into a depressed part of the furnace, whence the slag may be withdrawn, a fresh surface of the ore being continually exposed to the radiant heat. The volatilized zinc and the gases generated have exit by a separate outlet for condensation. The process has successfully produced good spelter at Trollhattan (Sweden), Sparsborg (Norway), Hartford (Connecticut), Nelson (British Columbia), and Hamborn (Westphalia). Many other types of electrical smelting have been proposed. Where cheap electrical energy is available, electrical smelting holds alluring promises of commercial success, but where cheap electrical power is not available the consumption of 12,000 kilowatt-hours per ton of metal is not a commercial proposition.

The extraction of zinc by wet processes.—Zinc cannot be precipitated from soln. of its salts by metals which do not oxidize at ordinary temp.; if other precipitants are used, the zinc is obtained as oxide; this must be mixed with carbon, and treated for zinc by the distillation process. The high cost of the wet processes of extraction involving the leaching of the ore for zinc salt, say sulphate, and its subsequent conversion of the sulphate to oxide, etc., was formerly prohibitive; but the growing demand for white pigments free from lead—e.g. lithophone, etc.—has rendered it possible to extract economically the zinc in the form of sulphate instead of as metal. The subject has been investigated by O. C. Ralston.¹² In 1851 J. Swindells proposed to roast zinc blende with sodium chloride in an oxidizing fire—*chloridizing roast*—extract the sodium sulphate, ferric chloride, and zinc chloride with water, precipitate the zinc hydroxide with lime; and then treat the hydroxide for zinc by the distillation process. A. C. Becquerel, W. Stahl, A. Gurlt, C. Höpfner, W. J. Huddle, and others have suggested modifications of the process. E. A. Parnell, and H. Pape roasted the sulphide ore to sulphate, leached with water, evaporated the pure zinc sulphate soln. to a paste, treated it with zinc sulphide, and heated the mixture to produce zinc oxide: $3\text{ZnSO}_4 + \text{ZnS} = 4\text{ZnO} + 4\text{SO}_2$. Soln. of sodium or ammonium chloride, or a suitable halogen salt, are available for dissolving out the lead sulphate or chloride.

J. Swinburne and E. A. Ashcroft chlorinated the sulphide with gaseous chlorine at a dull red heat, and modifications have been suggested by F. W. Traphagen, F. Rickard, A. Tixier, G. Carrara, and G. Mojana. Several processes have been devised in which the oxidized or roasted ore is treated with an acid. For example, F. M. Lyte, J. W. Worsey, J. Asbeck, E. Ferraris, P. Hart, etc., extracted the roasted ore with sulphuric acid; F. M. Lyte, etc., with hydrochloric acid; and E. A. Ashcroft, with a soln. of ferric chloride. C. Kellner, G. Dautin, C. Höpfner, V. Lindt, and H. Brandhorst, H. L. Sulman, used sulphurous acid. Soluble zinc hydrosulphite, $\text{Zn}(\text{HSO}_3)_2$, is formed, and the soln. is pumped into a tank where zinc sulphite, ZnSO_3 , is precipitated. This is roasted to oxide, and the sulphur dioxide used for the treatment of more ground ore. C. Schnabel, F. Ellershausen and R. W. Western, J. Wojtasiewitsch, etc. extracted the zinc oxide from the roasted ore by an ammoniacal soln. of ammonium carbonate. F. E. Elmore extracted lead and zinc from ores, etc., in which these metals occur as sulphides, by heating with an acid agent—sulphuric acid, or a soln. containing sulphuric acid or an alkali hydrosulphate, hydrochloric acid, etc.—which converts the lead into a soluble compound while the zinc sulphide remains unattacked.

Electrolytic processes for the extraction of zinc.—Many processes¹³ have

been devised in which the roasted zinc ore is treated with a solvent, and the zinc precipitated electrolytically from the soln., but (i) the high consumption of electrical energy necessary to deposit a strongly electropositive metal like zinc from its aq. soln. using an insoluble anode; (ii) the difficulties which are encountered at the cathode in preventing the formation of spongy zinc; and (iii) the difficulties in roasting, lixiviating, and purifying the liquors so as to produce an electrolyte of constant and definite composition, have all militated against the electrolytic zinc industry. In 1862, J. Dickson described a process for obtaining zinc from its ores by electrolysis; he proposed to deposit this metal from acid, aq., or alkaline soln. obtained by leaching roasted zinc ores, or by acting on the raw ores with acids. The suggested process attained no commercial success. In 1881, C. Luckow, and shortly afterwards C. Blas and E. Miest, devised processes for the direct extraction of zinc by utilizing zinc ore as the anode of an electrolytic bath—C. Luckow used a soln. of zinc and sodium chlorides as electrolyte, C. Blas and E. Miest used zinc nitrate. L. Létrange proposed to roast zinc blende at a low temp. to convert the sulphide to sulphate. The zinc was leached out with dil. sulphuric acid, and the soln. on electrolysis furnished zinc and sulphuric acid. The latter was to be used again in the process. E. W. von Siemens and J. G. Halske tried (i) leaching the calcined ore with acid ferric sulphate liquor, when zinc sulphide and oxide were dissolved—on electrolysis, the lixiviating liquor was regenerated; the zinc was spongy, and contaminated with much iron; and (ii) leaching with alum soln. when soluble basic aluminium salts were produced—on electrolysis, no acid was set free, but the lixiviating liquor was regenerated; the zinc deposit was not satisfactory. The best results were obtained by (iii) leaching with dil. sulphuric acid. Platinum electrodes, apart from their first cost, slowly dissolved in the technical liquor; and fouled the electrolyte; ferric oxide proved useless; but electrolytically deposited lead dioxide proved very stable chemically. V. Laszscynsky extracted roasted blende with the spent acid liquor from the electrolysis vat; dissolved ferrous iron was oxidized by air or potassium permanganate and precipitated by zinc oxide. Copper, arsenic, and cadmium were removed by hydrogen sulphide. The electrolysis current was 1500 amps. and 4 volts. In C. Höpfner's process, modified by Brunner-Mond Co. at Winnington, it is said that the roasted ore is mixed with water and ground to a pulp, which is treated, in the presence of carbon dioxide, with the calcium chloride waste-liquor from the ammonia-soda process: $\text{ZnO} + \text{CaCl}_2 + \text{CO}_2 \rightarrow \text{CaCO}_3 + \text{ZnCl}_2$. The iron, manganese, and electronegative metals are electrolyzed between graphite anodes, and rotating iron cathodes. The chlorine evolved at the anode is used in making bleaching powder; the zinc is said to be of 99.95 to 99.98 per cent. purity.

Zinc is far more electropositive than hydrogen, and it might be anticipated that cathodic deposition would not be possible in the presence of an appreciable amount of free acid; but highly purified zinc is but little affected by acids—even 10 per cent. sulphuric acid. Zinc can be successfully deposited from acid soln. when a high current density is used because of the high over-voltage necessary for the discharge of hydrogen from a zinc surface; and from an electrolyte containing zinc and hydrogen ions, the former is preferentially deposited. If the zinc be of a low degree of purity, the hydrogen over-voltage is low, and the zinc dissolves—iron, silver, nickel, copper, or arsenic act in this way and favour the dissolution of the zinc; while tin, cadmium, and lead are less active. Similarly if the electrolyte contains one of these metals, the discharge of hydrogen is favoured and the deposition of zinc hindered. A high current density raises the over-voltage, likewise also a low temp. Hence, these two conditions, coupled with a high zinc conc. and low acid conc. in the electrolyte, favour the deposition of zinc.

The zinc should deposit as a compact, coherent, greyish-white, finely crystalline mass with a slight tendency to give irregular growths at the edges; but it is very prone to form a spongy dark-coloured voluminous mass which is liable to cause short-circuiting, and introduce difficulties in melting owing to its enclosing some

electrolyte, and to its liability to oxidation. The conditions necessary for the production of a satisfactory deposit of zinc have been made clear by the work of M. Kiliani, F. Mylius and O. Fromm, and F. Förster and O. Günther. It is generally assumed that the formation of *spongy zinc* is favoured by the presence of zinc oxide, or basic zinc salts in the electrolyte, which disturbs the crystallization of the metallic zinc. A low acid conc. therefore favours the formation of spongy zinc. Depolarizers which form acids on reduction usually hinder sponge formation—*e.g.* hypochlorous or persulphuric acids; on the contrary, oxidizing agents which give neutral or basic substances on reduction favour sponge formation—*e.g.* hydrogen peroxide or nitrates. Sponge formation rapidly sets in when zinc is deposited from alkaline soln., although the excess of alkali prevents the precipitation of oxide or basic salt. A. Hantzsch, however, found that alkali zincate soln. are strongly hydrolyzed, and contain colloidal zinc hydroxide.

Whatever favours the discharge of hydrogen ions tends to produce spongy zinc, and once the sponge is deposited, the discharge of the H^+ -ions will increase since the over-voltage of hydrogen with zinc sponge is less than with the massive metal. A high current density and a low temp. favour the formation of a coherent deposit. The relation between the temp. and the current density—amps. per sq. dm.—required for the production of a coherent deposit of zinc, is illustrated diagrammatically in Fig. 5. Irregularities on the surface of the cathode cause the current density to fall locally. If the electrolyte be not renewed owing to poor circulation the soln. in the vicinity of the cathode is depleted of zinc ions, and there is a further fall in current density. Hence, a good circulation of the electrolyte, and the use of a moderately conc. soln. of the zinc salt—say 40–60 grms. per litre—favours the deposition of coherent zinc. The presence of an electro-negative metal in the electrolyte favours the formation of spongy zinc.

Several works have produced zinc by an electrolytic process—*e.g.* the Anaconda Co. has an electrolytic plant producing up to 100 tons per diem; another plant at Trail, British Columbia, can produce 40 tons per diem; another plant is working at Risdon, Tasmania; etc. According to F. Laist, F. F. Frick, J. O. Elton, and R. B. Caples, and S. Field, the process, in general outline, involves: (1) The calcination of the ores under special conditions to render the zinc soluble in sulphuric acid.

(2) The extraction of the zinc from the calcined ore by the acid-liquor from the electrolytic cells. The crude zinc sulphate soln. so produced contains about 1C per cent. of zinc sulphate; 0.05 per cent. of copper; 0.03, cadmium; 0.10, manganese; 0.05, iron; 0.01–0.001, cobalt; 0.01–0.001, nickel; as well as a little arsenic and antimony. Most of these impurities are highly detrimental to the successful electro-deposition of zinc. (3) The purification of the crude liquor is therefore of vital importance. Many patented methods have been devised. (4) The acidification of the purified liquor is necessary for economical electrolysis. This is effected by regenerated acid, and the acid liquor from the electrolysis cells. (5) The electrolysis is effected with lead anodes, and aluminium cathodes. (6) The deposited zinc is easily detached from the cathodes, and melted into ingots. The silver and lead in the residues remaining after the extraction of zinc from the calcined ore may be recovered as argentiferous lead. The electrodeposition of zinc has also been discussed by J. T. Ellsworth, and W. G. Traub.

The extraction of zinc by the electrolysis of fused salts.—The production of zinc by the electrolysis of the fused chloride has been investigated on a small and on a large scale. Fused zinc chloride is the principal product of J. Swinburne and E. A. Ashcroft's¹⁴ and C. E. Baker and A. W. Burwell's processes for the chlorine smelting of complex ores. It has also been proposed to prepare zinc chloride by the action of hydrochloric acid on the roasted ore, and to evaporate, fuse, and

FIG. 5.—Relation between Current Density and Temperature for the Deposition of Compact Zinc.

electrolyze the product. The difficulties connected with the electrolysis of fused zinc chloride have been investigated by R. Lorenz and co-workers. One of the chief difficulties is the preparation of anhydrous zinc chloride in vacuo. If zinc chloride be melted in an open crucible in air, and electrolyzed between carbon electrodes, much gas is evolved at both electrodes, zinc chloride vapours are evolved, the fused mass becomes turbid and a bad conductor, and no zinc is produced. If the zinc chloride be first mixed with sodium chloride the results are better, but still very bad. The trouble is due to the presence of moisture, derived largely from the flame gases. If the flame gases have no access to the melted mass which has been heated until fuming has ceased, hydrogen and oxygen are given off when the current is first passed; gradually, however, the evolution of hydrogen slackens off, and chlorine takes the place of the oxygen. Zinc is then produced, and the liquid remains clear. Hence, the water can be removed from zinc chloride by heat and electrolysis. The zinc chloride for this purpose was prepared by R. Lorenz by conducting the last stages of the evaporation in an atm. of hydrogen chloride. J. F. L. Vogel prepared this salt by evaporation. Another difficulty is the wear and tear on the electrolytic cell when heated externally. There is also a loss due to vaporization and the formation of a metal fog studied by S. Grünauer. The formation of fog is much reduced if a mixture of zinc and alkali chlorides be used; thus, at 600°, the percentage current efficiency was:

Electrolyte	ZnCl_2	$\text{ZnCl}_2 + \text{KCl}$	$\text{ZnCl}_2 + \text{NaCl}$	$\text{ZnCl}_2 + 1.2\text{NaCl}$
Current of efficiency	73.9–75.9	92.1–94.7	83.9–89.9	89.6–91.2

R. Suchy found the e.m.f. of the cell $\text{Zn} \mid \text{fused ZnCl}_2 \mid \text{Cl}_2$ to be:

	450°	500°	550°	600°	650°
Volts	1.643	1.611	1.576	1.535	1.494

and R. Lorenz found the decomposition voltage between 500° and 600° to be 1.49 volts. If the zinc chloride contains iron, that metal is deposited before the zinc, the current efficiency is lowered, and the progress of the electrolysis disturbed. G. Gallo obtained much better results by the electrolysis of fused zinc fluoride, m.p. 734°, or of a mixture of zinc fluoride and sodium chloride melting at about 500°.

The purification of zinc.—When ordinary zinc is dissolved in acids, a black residue remains. This was observed by J. Hellot¹⁵ in 1735, and by F. de Lassone in 1777. A. F. de Fourcroy stated that the black powder is iron carbide or plumbago; L. N. Vauquelin said the black powder is iron carbide, and L. J. Proust (1806) stated that “it is commonly thought that the black powder is charcoal or zinc carbide; it is nothing but arsenic mixed with a little lead and copper which the reducing power of the zinc precipitates in the metallic state.” He also added that commercial zinc contains iron and manganese. It is thought that the precipitate produced by hydrogen sulphide, and called by L. J. Proust arsenic, was most probably cadmium, a metal not discovered until 1817. A. Vogel said the residue contains carbon, iron, and lead; J. J. Berzelius and P. L. Dulong said that the impurities in zinc are lead, tin, copper, iron, cadmium, and sulphur. A. A. de la Rive found traces of tin, lead, cadmium, and sometimes more than one per cent. of iron. G. F. Rodwell, R. Funk, G. C. Wittstein, G. Barruel, and O. L. Erdmann and R. F. Marchand obtained similar results. R. Schindler reported the presence of iron, lead, arsenic, copper, nickel, cobalt, manganese, carbon, and a little uranium, but later observers have not confirmed the presence of uranium. H. W. F. Wackenroder did not confirm the statement of K. S. L. Hermann that zinc contains cobalt, nickel, and manganese, but he found copper; nor did he find carbon or arsenic, but he admits that arsenic might be present in small quantities. A. Erdmann said that it is impossible to separate completely lead from zinc by distillation because of the partial volatilization of lead. Many reports of the presence of sulphide in zinc are based on the production of hydrogen sulphide when commercial zinc

is treated with acids—e.g. M. Blancard—but M. J. Fordos and A. Gélis said that “the formation of hydrogen sulphide can be attributed only to the partial reduction of the sulphuric acid by the nascent hydrogen,” and subsequently V. A. Jacquelin attributed the hydrogen sulphide to the presence of sulphurous acid or other compounds of sulphur in the sulphuric acid, and doubted if the metal reduced the sulphuric acid. C. W. Eliot and F. H. Storer found every sample of zinc they treated gave hydrogen sulphide when dissolved in an acid free from sulphur, although C. J. B. Karsten, and F. Alger found samples free from sulphur. Many reports of arsenic in zinc are mal-observations due (1) to the confusion of the yellow sulphide of arsenic with the yellow sulphide of cadmium; (2) to the presence of arsenic in the acid employed for dissolving the zinc; and (3) to the use of tests of insufficient delicacy. C. W. Eliot and F. H. Storer found arsenic in the great majority of samples of commercial zinc, and traces of many impurities—carbon, sulphur, magnesium, manganese, aluminium, arsenic, antimony, cadmium, lead, iron, cobalt, nickel, bismuth, silver, and copper. F. Meyer, E. Jensch, F. Mylius and O. Fromm, A. Wagner, E. Reichardt, C. Stahlschmidt, F. Robineau and G. Rollin, G. Bonnet, etc., have also made observations on this subject. Commercial samples of zinc have approximately the composition:

	Zn	Pb	Fe	Cd	Sb, As, Sn
Electrolytic (English) . . .	99.97	0.007	0.010	0.004	—
Spelter (Welsh) . . .	97.22	1.30	1.42	0.03	0.01
Common spelter (English) . .	98.66	0.51	1.72	0.06	0.03
High-grade spelter (American)	99.96	0.02	0.02	—	—
Spelter (Silesian) . . .	98.92	1.03	0.02	0.02	0.01

T. R. Rolfe found that between 1913–16, the different brands of spelter contained between 0.31 and 2.03 per cent. of lead, and up to 0.19 per cent. of iron. C. J. B. Karsten obtained similar results in 1842. Spelter usually contains less than 0.2 per cent. of cadmium, although the latter may rise up to 2.0 per cent. Arsenic, antimony, copper, sulphur, and carbon are usually present in too small a proportion to affect the properties of the metal. Tin, copper, and aluminium may be found in remelted spelter. The purest zinc was found by G. H. Williams, W. M. Burton, and E. W. Morley to contain carbon. C. Viollette and R. Funk said that the carbon is free, not combined with zinc as R. Schindler supposed. C. Künzel found zinc prepared from scrap-zinc contained 0.2 to 0.3 per cent. of chlorine. R. Funk found 0 to 2.5 parts of sulphur in 10 million parts of zinc probably suspended therein as zinc sulphide. K. Friedrich found small proportions of silver in zinc; and A. Streng found thallium in the zinc from Vieille Montagne. D. Pacini found that zinc is more readily freed than other metals from radioactive impurities. G. D. Scholl discussed the impurities in electrolytic zinc.

Lead in spelter is considered objectionable for many purposes. When the spelter contains 2 to 3 per cent. of lead, it is refined by liquation. A large bath—holding 20–30 tons—is kept molten for some days at as low a temp. as possible. The bulk of the lead accumulates by gravity at the bottom, and a better grade of zinc, with 0.8 to 1.0 per cent. of lead, accumulates at the top. This 0.8 to 1.0 per cent. represents the solubility of lead in molten zinc just above its m.p. The insoluble lead settles in minute globules. An alloy of iron and zinc also settles just above the lead, so that some iron is simultaneously removed from the spelter. Less fusible impurities float as a scum on the molten metal, and can be skimmed off. Re-distillation is sometimes used for recovering zinc from alloys rich in lead.

G. C. Stone has reported analyses of American splters. In 1911, the American Society for Testing Materials suggested the following four grades of commercial spelter:

	Pb	Fe	Cu	Maximum total
A.—High grade . . .	0.07	0.03	0.05	0.10
B.—Intermediate . . .	0.20	0.03	0.05	0.50
C.—Special, brass . . .	0.75	0.04	0.75	1.20
D.—Prime Western . . .	1.50	0.08	—	—

G. C. Wittstein recommended purifying zinc by distilling the metal once or twice from a clay retort; V. A. Jacquelin distilled the metal in a stream of hydrogen. J. J. Berzelius and P. L. Dulong added that distillation does not remove the more volatile metals—arsenic, antimony, cadmium, and lead—and the zinc after distillation still retains these impurities. H. N. Morse and W. M. Burton distilled commercial zinc in vacuo, using a glass tube divided into three compartments. The metal was distilled from the first compartment into the second and third; when about one-fourth still remained in the first compartment, and about one-tenth had passed into the third, the operation was stopped, and repeated four times on the contents of the second compartment. The metal was spectroscopically free from lead, cadmium, tin, and indium. M. J. B. Orfila and A. Meillet fused granulated zinc with a little nitre to remove arsenic and iron. J. S. Stas removed carbon from zinc by melting it with litharge—this introduces lead into the zinc. R. Funk removed sulphur and carbon by melting the metal many times and filtering it through asbestos. R. D. Bohannon obtained iron-free zinc by reducing zinc chloride with sodium. J. W. Gunning, G. Bonnet and M. Schwake, W. Merton, and F. Stolba recommended fusing zinc with sulphur or a mixture of sulphur and sodium carbonate to remove arsenic. P. Lobmann recommended removing arsenic by fusing the metal with potassium cyanide; C. Mann, fusion with borax; F. Selmi, fusion with ammonium chloride; O. Hehner, and L. T. Thorne and E. H. Jeffers, fusion with sodium; T. l'Hôte, fusion with dried magnesium chloride; and H. Lescœur, fusion with nitre, or with zinc chloride. F. Mylius and O. Fromm said that purification by fusion with nitre or sulphur, or by distillation, is incomplete. J. Myers has claimed to have prepared zinc with but one part of impurity in 100,000 parts of metal.

Zinc of a high degree of purity can be obtained from zinc-ethyl, and when electrolyzed with platinum as anode and zinc as cathode, the electro-deposited metal contains a trace of platinum; but, by using a zinc anode, and working with a basic soln. and low current density spongy zinc is obtained, which, by many repetitions of the process, is free from foreign metals. The spongy metals should be well washed, and freed from oxide, by fusion with ammonium chloride, and finally, by sublimation in vacuo.

The electrolytic refining of zinc, using sheet zinc as cathode, and plates of the impure metal as anode, conducted as in the case of copper refining, has been only partially successful. The operation is not usually economical unless the anode slimes are rich in noble metals, as is the case with the zinc-silver alloy obtained in Parkes' process.¹⁶ In any case, however, the economic margin is small, and the older separation by distillation has proved to be simpler and cheaper; but, for small quantities, the electrolysis of the highly purified chloride or sulphate can furnish a metal of 99.998 per cent. purity.

The extraction of cadmium.—G. Städler,¹⁷ and F. O. Döltz and C. A. Graumann showed that when cadmiferous zinc ores are roasted, a certain amount of cadmium is lost, either by the volatilization of the oxide, or by the reduction of the oxide and volatilization of the metal. E. Jensch reports a loss of nearly 62 per cent. of the cadmium in this way. The cadmium oxide in the roasted zinc ores is reduced with the zinc in the retorts, and owing to the great volatility of the metal, the cadmium distils first, and imparts a brownish tinge to the flame of carbon monoxide burning at the mouth of the retort before the bluish-green tinge of zinc appears. Cadmium accumulates partly in the liquid zinc in the condenser, and partly in the zinc fume in the prolong. When it is desired to recover the cadmium, the fraction which collects in the condenser and prolong during the first two hours is reserved. The cadmium is recovered from the zinc fume, by mixing it with coke breeze, or charcoal as described by C. F. Hollunder, and distilling it fractionally from the mixture. The temp. of the retort is kept at about 800°, so that little more than cadmium oxide is reduced. In this way, a metal over 99.5 per cent. purity is obtained. H. Moissan and A. J. P. O'Farrelley distilled the cadmium from its alloy by heating in an electric-arc furnace. H. N. Morse and H. C. Jones heated

cadmium powder in a stream of purified hydrogen for a long time, and then distilled it in vacuo by the process employed by H. N. Morse and W. M. Burton for zinc. The sixth distillate was spectroscopically free from impurities.

Wet methods of extraction have not come into use. They were used at first by F. Stromeyer, J. F. John, and W. Herapath. F. Stromeyer dissolved the cadmiferous zinc in dil. sulphuric acid; precipitated the cadmium sulphide by treatment with hydrogen sulphide; dissolved the washed sulphide in conc. hydrochloric acid; evaporated the soln. to expel the excess of acid; and treated the soln. with ammonium carbonate in slight excess so as to dissolve any copper or zinc which might be present. The washed precipitate was ignited to convert it to cadmium oxide, which was then mixed with carbon and the cadmium distilled from a zinc retort. Another method proposed by G. Jäckel depends on the fact that when cadmiferous zinc fume is treated with hydrochloric acid, the zinc dissolves first and cadmium can be precipitated from its soln. in that acid by metallic zinc. Hence, if cadmiferous zinc fume be treated with insufficient acid to dissolve all the zinc, the excess of zinc will precipitate any cadmium which may have passed into soln. The lead will remain with the cadmium as a residue. The residue is then digested with hydrochloric acid until cadmium begins to dissolve, thus showing that all the zinc has been dissolved. The cadmium is precipitated from a soln. by zinc rods. The mixture of lead and cadmium is then distilled. The soln. of zinc chloride is treated with lime when zinc hydroxide is precipitated.

B. Kosmann treated the zinc dust with a soln. of neutral ammonium carbonate—the zinc dissolved, the cadmium and lead remained as insoluble carbonates. The residue was heated to convert the lead into oxide, and then digested with a soln. of lead acetate, to dissolve the lead oxide. The residual cadmium carbonate was converted into sulphide by dissolving it in dil. sulphuric acid and treating it with hydrogen sulphide; or into oxide by treating it with nitric acid, and subsequent evaporation of the soln., and ignition of the residue. He also extracted the fume first with water, and then with dil. sulphuric acid. The two soln. were mixed and heated to precipitate iron and calcium sulphate; the soln. was diluted and the cadmium precipitated with the arsenic as sulphide. When the mixed sulphide was roasted, the arsenic was volatilized, and cadmium oxide remained.

D. Lance treated the carbonate or oxidized ore with an aq. soln. of an alkylamine alone or in presence of aq. ammonia, and when gradually heated, the zinc is first precipitated as hydroxide, then follows the cadmium hydroxide. W. G. Rumbold and G. Patchin extracted the oxidized ore with an acid soln. of ferric sulphate, and subsequently precipitated the cadmium. O. Unger treated the oxidized ore with a soln. of zinc chloride and precipitated the cadmium by means of metallic zinc. R. Biewend found that metallic cadmium and cadmium alloys, when heated in a glass tube closed at one end, yield a cadmium-mirror, accompanied by a sublimate of cadmium oxide, dark grey when hot, and brown when cold. In the case of zinc ores containing cadmium, potassium oxalate is added as a reducing agent; while calamine, an addition of spathic iron ore, is preferable. From the more volatile sublimates and distillates, that of cadmium can be separated by igniting in a current of air, when the former are volatilized, whilst the latter is converted into cadmium oxide, which is not readily volatile.

H. R. Hanley described a wet process in which the raw material is first obtained in sulphuric acid soln. This is treated with limestone and the precipitated mud—containing copper, cadmium, and zinc—is digested with dil. sulphuric acid, at 60°, and the soln. separated from the cupriferous mud. Cadmium is precipitated on sheet zinc as sponge-cadmium. This is dissolved in an acid cadmium electrolyte. Iron is precipitated with hydrated lime. Thallium, if present, is removed by sodium dichromate in neutral soln. If arsenic is present it is removed by adding ferrous sulphate to the soln., and both iron and arsenic are precipitated together by hydrated lime. The soln. is then acidified, and electrolyzed. The cadmium deposit is finally melted and ingoted.

E. A. Partridge,¹⁸ H. N. Morse and H. C. Jones, and J. E. Bucher purified cadmium by distillation in vacuo up to nine times. W. S. Lorimer and E. F. Smith electrolyzed a soln. of cadmium oxide in potassium cyanide; W. L. Hardin electrolyzed soln. of cadmium chloride or bromide, as did also W. Borchers, P. Denso, A. Brand, F. Mylius and R. Funk, H. N. Morse and H. C. Jones, and R. Lorenz.

G. Bredig,¹⁹ D. Zavrieff, and W. Tichomiroff and A. Lidoff obtained **colloidal zinc** by forming an electric arc with zinc wires under water. T. Svedberg made colloidal zinc and cadmium by connecting a glass condenser of 225 sq. cm. surface with the induction coil and attaching the secondary poles to the electrodes, which are immersed in propyl or isobutyl alcohol contained in a porcelain dish. The zinc was used in a granular form or as wire clippings. When the current is passed, sparks play between the metal particles, and in the course of a few minutes dark-coloured soln. are obtained. These contain no large particles and hence need not be filtered. The isobutyl alcohol is brownish-red in transmitted light and greyish-black in reflected light. G. Bredig also made **colloidal cadmium**, and found that the zinc hydrosol is less stable than the cadmium hydrosol. O. Knoblauch noted Bredig's colloid has photoelectric dispersive powers.

§ 4. The Physical Properties of Zinc

Zinc is a greyish-white or bluish-white metal, and it is susceptible of a high degree of polish. The cleavage planes on a freshly fractured surface of an ingot of zinc have a brilliant lustre. R. Hennig¹ found the composition of cast zinc to be uniform in a high degree. A. Laurent and C. Holms observed the formation of small rhombic **crystals** of the metal in cracks in the fireclay tubes in which the zinc had been distilled. These rhombic crystals contained four per cent. of iron. C. F. Plattner, W. Kayser, C. W. Zenger, F. Stolba, and J. Nöggerath likewise found long regular six-sided prisms in the walls of drusy cavities. J. Nicklès, and C. W. Zenger obtained pentagonal dodecahedrons by distilling zinc in a stream of hydrogen, but the crystals were not measured. G. H. Williams and W. M. Burton, G. W. A. Kahlbaum, K. Roth and P. Siedler, and P. Termier obtained crystals by distilling the metal in vacuo at a low temp. S. P. Sharples found zinc crystals were developed at the hot junction of a thermoelectric battery. H. N. Warren placed a magnesium rod wrapped in coils of asbestos paper in a soln. of a zinc salt, and found that a zinc-tree was developed. According to G. Bird, if a zinc plate dips in a soln. of sodium chloride contained in a porous pot dipping in a soln. of a zinc salt, in which is fitted a platinum or copper plate, when the circuit is closed, crystals of zinc are formed. R. Lorenz obtained six-sided crystals of zinc by the electrolysis of the molten chloride; while F. Mylius and O. Fromm obtained analogous results. A. Saposhnikoff placed two glass rods in a photographic dish, and arranged a glass plate to which a copper and a zinc wire were fixed to serve as electrodes. The glass plate rested on the glass rods submerged in a soln. of zinc chloride or sulphate. Microscopic crystals of zinc were produced on the glass plate. D. Tommasi, and T. Tommasina electrolyzed water with a zinc plate cathode and a thin wire anode and obtained crystals of zinc. R. Lüpke electrolyzed a conc. soln. of zinc chloride in a U-tube fitted with two platinum electrodes. The lower part of the tube was soon filled with dendrites of zinc. W. Holtz obtained a zinc-tree on a small zinc cathode in a soln. of zinc chloride, and connected for electrolysis with a couple of Leclanché cells; and J. Myers electrolyzed a soln. of zinc hydroxide in aq. ammonia with two Bunsen cells. F. Schidlowsky obtained microscopic dendrites by using a zinc anode and a cathode dipping in water. J. Czochralsky compared the **speed of crystallization** of zinc with that of tin and of lead; and G. Tammann and Q. A. Mansuri measured the velocity of crystallization of the compressed powder at different temp. and in different atm.

The rhombohedral crystals of zinc were found by G. H. Williams and W. M. Burton to belong to the hexagonal system with axial the ratio $a : c = 1 : 1.3564$. According to G. H. Williams, P. Termier, and G. Linck, zinc and cadmium are isomorphous, and form a eutropic series with magnesium. R. Rieth and F. Beilstein found zinc-sodium alloys, low in sodium, form cubic crystals; and with arsenic

octahedral crystals. J. P. Cooke also found that crystals with 18.82 per cent. of arsenic formed octahedral crystals belonging to the cubic system. The proportion of arsenic in these crystals, added J. P. Cooke, is so much smaller than the amount required to form any probable definite compound, that there can be little doubt that it is present as an impurity, and that the octahedrons are isomorphous mixtures of the two elements. The presence of a certain amount of impurity seems to favour metallic crystallization; and it is possible that it may be the disposing cause in this case, inducing as it were "a monometric condition of the zinc." If arsenic really can make zinc crystallize in the cubic system, then zinc is probably dimorphous. C. W. de la Rue found that when commercial zinc plates are dissolved in a galvanic apparatus, rhombic prisms of a lead-copper-zinc alloy remain. F. H. Storer found that zinc alloys with up to 30 per cent. of copper crystallize in octahedrons belonging to the cubic system.

A. W. Hull found that **X-radiograms** of zinc corresponded with a close-packed hexagonal lattice. They do not fit the hexagonal lattice with the axial ratio 1.356, but require an axial ratio 1.860. The side of the elementary triangular prism is 2.670 Å., and the distance between the nearest atoms in the basal plane is 2.670 Å., and in the pyramid planes, 2.920 Å. The computed density obtained by dividing the mass of the atoms in an elementary cell by the vol. of the cell is 7.04, the observed value is 7.142. L. Hamburger made an ultra-microscopic examination of thin films of zinc. S. Nishikawa and G. Asahara, and M. Ettisch and co-workers studied the effect of rolling and annealing on the X-radiogram of zinc. W. L. Bragg found the atomic diameter to be 2.65 Å. The zinc lattice has been studied by M. Polanyi, A. W. Hull and W. P. Davey, etc.

The **fracture** of an ingot of ordinary zinc presents numerous brilliant crystal facets set at various angles, and more or less foliated—in some cases the crystals are in confused masses, in others, the crystal facets are large, even, and distinct. In his paper: *Zur Kenntnis der Moleculareigenschaften des Zinks*, P. A. Bolley showed that the structure of the ingot is modified considerably by the temp. at which the metal is cast. For example, when poured just above the m.p. and allowed to cool slowly, the fracture is finely granular; if heated to redness before pouring, the fracture is more coarsely crystalline; and if heated to a still higher temp., the fracture is coarsely crystalline, and the rate of cooling has but little influence on the crystals. Other things being equal, the slower the cooling the larger the crystals, so that an ingot will appear more coarsely crystalline towards the centre, where the cooling is slowest. According to O. Meyer, and E. H. Schulz and O. Zeller, the fracture of zinc which has been heated to 145°–165° is coarsely crystalline. O. Mügge has studied the **cleavage** of zinc. Zinc which has been crystallized by annealing between 130° and 300° was found by S. Kalischer to lose its ring, and the bending is accompanied by a sound similar to that which occurs with tin.

According to F. Stolba, if zinc be just melted in a crucible and poured on to a non-conducting surface of, say, asbestos, and the liquid portion then run off from that which has solidified, a crust of hexagonal pyramidal crystals will be obtained. Obviously, the external geometrical form of a crystal is developed in a liquid or plastic viscid solid. When a cooling liquid solidifies, the growing crystals interfere with one another, and the resulting solid appears to be a mass of irregular polygons. Most metals are aggregates of crystals grown under these conditions, and when a polished surface is lightly etched, the metal appears to be composed of a number of grains irregular in size and shape; but if deeply etched, the grains themselves also differ in texture. The texture is due to a number of small facets in each grain; the facets are similarly oriented in any one grain so that the general surface of the grain reflects light in a particular direction. Crystallites or incipient crystal forms are common and show as a cross-hatching of the surface. The dendritic zinc crystals were studied by W. Campbell, H. Bearens, etc. The twinning of idiomorphic crystals also appears on etched surfaces.

When the metal is annealed, the crystallitic structure (composed of crystal skeletons) is replaced by a well-defined crystalline structure. According to G. Masing, on heating zinc that has been cold-worked, primary recrystallization of the metal begins immediately throughout the mass without the formation of nuclei. As the temp. rises to 170° – 190° nuclei of secondary crystals begin to appear in the mass of primary crystals, and these gradually increase in number and size if the heating is continued slowly until the whole of the metal consists of a mass of large secondary crystals which are coarser the lower the temp. of formation and the longer the heating. If the metal is subjected to a secondary deformation, the secondary crystal nuclei begin to form at 70° . M. Ettisch and co-workers found the crystallites in soft wires are arranged irregularly, and in hard-drawn wires regularly. G. I. Petrenko observed that a polished surface of zinc, cooled slowly from above its m.p. to 180° exhibited large polyhedra (separate or interpenetrating) on which were promiscuously disposed comparatively small ones. The latter were more abundant when the metal was quenched from 360° to 330° , but completely covered the surfaces of the large crystals when the metal was cooled to just below 300° . The phenomenon was reversible, and was regarded as indicating the occurrence of an allotropic transformation between 290° and 300° . K. E. Bingham studied the microstructure of zinc quenched in the ranges of temp. supposed to belong to assumed α -, β -, and γ -forms of zinc—and found that this hypothesis fits her observations. D. H. Ingalls studied the relation between the mechanical properties and the microstructure.

G. Timofeeff showed that zinc which has been squeezed in a vice appears homogeneous, and under the microscope no crystals are discernible; G. T. Beilby also showed that the polished surface of the crystalline metal is covered by an amorphous glass-like film which can be removed by a suitable etching liquid, so as to expose the subjacent crystalline structure. When the non-crystalline metal is annealed, recrystallization sets in. S. Kalischer observed that recrystallization begins at about 150° . According to G. Tammann, large crystals of zinc appear at 75° , and their size increases as the temp. rises to 250° , and increases again when reheated to 350° ; Z. Jeffries and R. S. Archer state that the lowest temp. at which the recrystallization of cold-worked zinc has been observed is the room temp. F. Novak found that, within certain limits, the higher the annealing temp. of zinc, the more rapid the crystallization. At any given temp., the size of the crystal grains is limited by the duration of heating. H. Behrens found recrystallization is completed at 200° . The large individual crystals of cast zinc become striated under a slight shock. J. A. Ewing and W. Rosenhain found commercial sheet zinc has no large crystals, but is tough, and when heated to 200° for half an hour, it is crystalline, brittle, and, when bent, breaks along definite cleavage planes, and emits a "cry" like tin. They also found that when the metal is strained beyond its elastic limit, the surface of each crystalline grain becomes marked by one or more systems of lines generally running straight and parallel. The lines or slip-bands are slips along cleavage or gilding planes in the crystal. The directions of the lines change from grain to grain. The lines become more and more numerous and emphatic, the greater the strain. A. Lacroix found the **percussion figure** of zinc shows lines parallel to the sides of the hexagon. H. Behrens, and J. A. Ewing and W. Rosenhain have studied the twinning of zinc crystals. According to E. Cohen and K. Inouye, when a strip of zinc with a cross etched on its surface by an acid is kept in contact with another unetched strip of zinc by press. at 100° – 180° for 17–48 hrs., a similar cross will be developed on the second strip. This does not occur at ordinary temp.

For etching zinc or cadmium surfaces, G. Timofeeff used a few drops of a mixture of 94 per cent. nitric acid and 6 per cent. chromic acid, added to 50 or 100 c.c. of water; G. H. Gulliver recommended a soln. of one part of iodine, 3 parts of potassium iodide, and 10 parts of water. J. Czochralsky recommended a highly conc. soln. of chromic acid. G. Cartaud used a soln. of picric acid in acetone; S. Kalischer used sulphuric acid with a little nitric acid, or a soln. of cupric sulphate. Five to ten per cent. soln. of alkali hydroxide are often used. H. H. Hayes recommended nitric acid of sp. gr. 1.5.

If over 0.1 per cent. of iron is present, distinct crystallites are produced which are considered to be the cause of the light specks on the crystal faces of a fractured ingot of zinc. If the zinc contains lead, the latter is rejected by the freezing zinc, and forms minute globules often occupying the cleavage cracks caused by the contraction of the crystalline zinc during solidification. If zinc oxide be present, it often collects at the crystal boundaries, making them appear thick. G. Cartaud has studied the effect of 0.5 per cent. additions of silver, lead, copper, bismuth, cadmium, tin, arsenic, antimony, iron, aluminium, manganese, nickel, and phosphorus on the metal. E. A. Lewis, E. H. Schulz and R. Melaun, and F. Novak also studied the effect of impurities on the crystal structure of zinc.

The reported values for the **specific gravity** of zinc vary from R. Schiff's 26.966 at 12° to P. A. Bolley's and W. C. Roberts-Austen and J. Wrightson's 7.20 . The best representative value is 7.142 . G. W. A. Kahlbaum and co-workers found the sp. gr. of distilled zinc to be 6.9225 at $20^\circ/4^\circ$, and after compression up to $10,000$ atm., 7.12722 . According to W. Spring, the sp. gr. of zinc is 7.142 at 16° , and after compression for three weeks at $20,000$ atm., 7.153 , and after a repetition of the treatment, 7.150 . C. J. B. Karsten found the sp. gr. of rolled commercial zinc is 7.1908 , and after hammering and rolling the sp. gr. may reach 7.2 or 7.3 . According to S. Kalischer, the sp. gr. of ordinary zinc at 0° is 7.1812 , and when crystallized, 7.1841 . P. A. Bolley proved that there is no variation in the sp. gr. of zinc at a given temp. before and after fusion; any variation which may have been observed is entirely due to the development of minute cavities in the metal; so that a piece of zinc weighed whole has a lower apparent sp. gr. than when it is fractured into smaller pieces. A. Matthiessen found that the sp. gr. of redistilled arsenic-free zinc is 7.144 at 15.5° ; after fusion 7.150 at 14.4° ; and after another fusion 7.149 at 15° . The original piece before distillation had a sp. gr. 7.148 at 15° . P. A. Bolley found the sp. gr. is lower when the metal is cast at a high than when cast at a low temp. Thus, when poured near its m.p. the sp. gr. zinc is 7.178 when rapidly cooled, and 7.145 when slowly cooled; while when poured almost at a red heat, the sp. gr. was 7.109 if rapidly cooled, and 7.120 if slowly cooled. C. F. Rammelsberg on the contrary found that the sp. gr. of cast zinc is dependent neither on the temp. of pouring nor on the mode of cooling; he obtained between 7.10 and 7.16 for the slowly cooled cast metal, and between 7.04 and 7.14 for the rapidly cooled metal. K. E. Bingham slowly cooled a piece of rolled zinc, and heated portions to different temp. for 30 mins. The samples were then quenched. Samples heated to 50° had a sp. gr. 7.080 ; to 100° , 7.086 ; and to 150° , 7.089 . There was an abrupt rise in sp. gr. to 7.16 for samples heated to 150° and higher temp. as indicated in Fig. 6.

FIG. 6.—The Specific Gravity and Scleroscopic Hardness of Zinc annealed at different Temperatures.

T. M. Lowry and R. G. Parker found that as with most metals the sp. gr. of zinc is reduced by working. Thus, the sp. gr. of purified zinc was 7.1374 , and that of the filings from the same metal 7.1323 . When completely annealed, the worked metal contracts, but when partially annealed there is an expansion. The sp. gr. of zinc was found by W. C. Roberts-Austen to change from 7.2 to 6.51 when melted: this corresponds with a contraction during solidification. C. M. Marx, and F. Nies and A. Winkelmann noted the contraction of molten zinc in the act of solidification. According to M.

Töpler, a gram of zinc expands 0.010 c.c. in passing from the solid to the liquid state. L. Playfair and J. P. Joule gave 6.512 for the sp. gr. of melted zinc; G. Quincke gave 6.9 . T. R. Hogness gave $D = 6.59 - 0.00097(\theta - 419)$ for the sp. gr.

of molten zinc at θ° . P. Pascal and J. Jouniaux found the sp. gr. of liquid zinc in an inert gas at the m.p. 418° to be 6.92; at 600° , 6.81; and at 800° , 6.57. According to W. T. Cooke, the **vapour density** of zinc in an atm. of nitrogen is 32.5 (hydrogen unity); in an atm. of argon, 36.4; in an atm. of hydrogen, 36.4; and in an atm. of helium, 35.8. According to V. Meyer and J. Mensching's measurements, the vap. density of zinc vapour 2.36 (air unity) corresponds with a monatomic molecule.

E. Donath and J. Mayrhofer have studied the **atomic volume** of zinc. W. Thomson, and G. Jäger made estimates of the **molecular diameter**. The former deduced that "plates of zinc and copper so thin as 4×10^{-8} cms., and placed as short a distance as 4×10^{-8} cms. from one another, form a mixture closely approaching to a molecular combination, if indeed plates so thin could be made without splitting atoms." W. L. Bragg gave $0.132\mu\mu$ for the at. radius of the at. spheres; M. N. Saha, 0.077. K. F. Slotte gave 6.3×10^{-9} cms., for the edge of the molecule assumed to be a cube. C. T. Heycock and F. H. Neville determined the **molecular weight** of zinc dissolved in cadmium, tin, lead, and bismuth.

According to E. Cohen,³ when zinc of sp. gr. 7.129 is heated in the presence of a sat. soln. of zinc sulphate for 33 hrs. at 100° , its sp. gr. falls to 7.102; hence, it was inferred that ordinary zinc is in a metastable condition and that the allotropic modification formed at the higher temp. passes slowly at ordinary temp. into a stable variety having a sp. gr. 6.92. There are indications that the transition temp. is near 64.9° .

Ordinary zinc is a comparatively soft metal, though much harder than tin and silver, and it clogs a file; but when pure, zinc is softer than silver. According to C. Margot,⁴ if glass is quite dry, it can be scratched by zinc. According to F. C. Calvert and R. Johnson, if the **hardness** of cast iron be 1000, that of zinc is 183. A. Kürth gave 46.0, C. A. Edwards 45.5, for the hardness of zinc on Brinell's scale. The Brinell's hardness of cast zinc is 38.1, copper 40.0, and silver 24.8. Purified zinc is appreciably hardened by quenching in water after casting. According to T. K. Rose, zinc is hardened by mechanical treatment—*e.g.* rolling—and requires annealing for half an hour at 125° . Zinc hardened by rolling is in an unstable condition at ordinary temp., and gradually changes to the soft state. Thus, the scleroscope hardness of a sample of rolled zinc was 36.0, and after 97 days the hardness had fallen to 31.0. K. E. Bingham measured the hardness of zinc heated to different temp. for 30 mins. and then suddenly quenched. The Brinell's hardness tests were somewhat erratic, but the scleroscopic tests are represented by dotted curve, Fig. 6. There are critical points at 160° and 330° . P. Ludwik found the curve representing the variation of hardness with temp. is continuous, and slightly convex towards the temp. curves, whether the metal has been slowly or rapidly cooled. The hardness of zinc is usually raised by the presence of impurities: thus E. A. Lewis found the hardness of zinc is raised by phosphorus; C. Karmarsh found a similar result with 0.1 per cent. of iron and 0.5 per cent. of copper; while F. Novak found 0.25 per cent. of cadmium makes zinc harder, and over 0.5 per cent. makes the zinc softer. J. R. Rydberg, P. Ludwik, A. Kürth, and S. Bottone have also made measurements of the hardness of zinc. J. Okubo found the scleroscopic hardness of zinc to be 10.8 when that of lead is 1.35; he also measured the **coefficient of restitution on impact**.

K. Iokibe and S. Sakai⁵ found the coeff. of **viscosity** of zinc to be 410.7×10^8 at 22° . K. Honda and S. Konno gave 27.4×10^8 at 20° for the coeff. of normal viscosity of rolled zinc; and 9.27×10^8 for the metal annealed at 200° . Measurements were also made by C. E. Guye and co-workers. G. Quincke found the **surface tension** of zinc in air at 360° to be 967.4 dynes per cm., and the **capillary constant** $a^2=28.6$ sq. mm.; the corresponding numbers in carbon dioxide are 103.7 and 30.6 respectively. Between 580° and 630° , the surface tension of zinc is 707.5 dynes per cm., and the capillary constant 25.54 sq. mm. S. W. Smith gave 707.5 dynes per cm. for the surface tension of zinc at 580° – 630° , and $a^2=24.8$. T. R. Hogness gave $\sigma=758-0.090(\theta-419)$ for the surface tension of molten zinc at θ° . I. Traube

gave 108,900 megabars or 10^6 dynes per sq. cm. for the **internal pressure** of solid zinc. G. Meyer gave for the **diffusion coefficient** of zinc in mercury, in sq. cm. per day, $k=2.09$ at 15° ; and M. von Wogau, $k=2.18$ at 11.5° , and $k=2.90$ at 99.2° . The diffusion of copper into molten zinc was studied by O. F. Hudson, and H. Weiss. According to A. Masson, the **velocity of sound** in zinc is 3698.5 metres per sec. when the velocity in air is 332 metres per sec.; G. G. Gerosa gave 3680.9 metres per sec. for the velocity of sound in zinc at 13° . S. Kalischer found that rolled zinc loses its sonorous ring when heated, and the ring then becomes as dull as lead—the higher the temp. the duller the sound.

According to H. Behrens,⁶ highly purified zinc is malleable and may be rolled into sheets at ordinary temp., but the commercial metal is then moderately hard and brittle. The **malleability** of commercial zinc lies between that of lead and of iron, and the **ductility** between that of copper and of tin. An ingot or cake of commercial zinc can be easily broken to pieces under the hammer. The malleability of zinc is very much greater than that of bismuth or antimony. The elongation in the tensile strength test can be regarded as a measure of ductility—Fig. 7. H. F. Moore found that sheet zinc is more ductile with the grain than across the grain (*i.e.* perpendicular to the direction of rolling) and that the ductility of zinc is less than that of mild steel. According to W. Campbell, if hammered or rolled cold, the crystalline structure is broken up and the metal splits and breaks up. Above 205° , zinc is so brittle that it may be readily pulverized by trituration in an iron mortar. According to A. F. de Fourcroy, the fact that zinc can be pulverized in a mortar when warmed to a temp. below its m.p. was known to P. J. Macquer in 1801. In 1805, C. Hobson and C. Sylvester made the important discovery that commercial zinc, between 100° and 150° , becomes malleable and ductile, and they obtained a patent for “a method of manufacturing the metal called zinc into wire and into vessels,” for zinc can then be rolled into sheets and drawn into wire, and, after cooling, these properties are to some extent retained. E. H. Schulz and R. Fiedler found samples of zinc with the notched bar impact test gave results varying from 0.55 to 0.75 kgrm. metres per sq. cm. The **resistance to impact** decreased with fall of temp.

E. Prost and A. van de Castele found that the ductility of zinc is appreciably lowered by 0.25 per cent. of cadmium; 0.02 per cent. of arsenic makes zinc harder and more brittle; antimony acts like arsenic, but is not so harmful; 0.01 per cent. of tin is objectionable; copper does not harden zinc if less than 0.08 per cent. is present, but the zinc cannot be rolled if 0.19 per cent. is present; 0.12 per cent. of iron is permissible; and 1.0 to 1.25 per cent. of lead does not interfere with rolling, but a slight increase affects the malleability—the excess of lead remains unalloyed, and forms patches on the sheet.

It has been suggested that the phenomenon near 170° is possibly due to the transformation of zinc from one allotropic form to another. Besides E. Cohen's two **allotropic forms** of zinc (*vide supra*) with a transition about 64.9° , there is a third form with a transition about 170° , and a fourth with a transition at about 310° . These two latter transition points are in agreement with observations on the electrical resistance, electrolytic potential, sp. gr., hardness, mechanical properties, and microstructure. M. P. Lastschenko found a change in the sp. ht. curve of zinc in the vicinity of 340° – 350° , which he interpreted as corresponding with an allotropic change in the nature of the metal. The heat of transformation is estimated to be 190 cal. per gram-atom of zinc. Neglecting E. Cohen and W. D. Helder mann's transition point, C. Benedicks assumed that zinc is trimorphous, with enantiotropic transition points:

P. A. Bolley stated that zinc which has been cast at a low temp. is more readily attacked by acids than the metal cast at a red heat; and K. E. Bingham found that zinc quenched from the range of temp. of γ -zinc is more difficult to etch than zinc quenched from the ranges of the β - or α -forms. As previously indicated, C. Benedicks and R. Arpi stated that previous observations on the discontinuity in the

electrical resistance of zinc between 170° and 350° is due to the presence of cadmium or lead as impurities, but K. E. Bingham regards this as an improbable explanation. For criticisms *vide* allotropic copper.

According to C. Mentzel, the malleability of zinc depends to some extent on the temp. at which it has been melted, for it is more malleable if poured near its m.p. than if cast at a higher temp. A. Martens found the malleability to decrease rapidly as the temp. rises above 150° ; and, according to H. le Chatelier, the malleability or ductility changes with temp., thus:

		15°	70°	150°	200°	250°	300°
Elongation . . .		16.5	300	500	40	3	2 per cent.
Breaking load . . .		12.4	3.6	2.4	0.9	0.7	0.6 kgrm. per sq. mm.

Zinc is hardened by rolling or mechanical treatment generally, but the hardness can be removed by annealing as previously indicated, soft sheet zinc becomes brittle after it has been heated to a temp. bordering on its m.p. Impurities in the metal have a marked influence on the malleability of zinc. Thus, C. Karmarsch found that zinc with 3 per cent. of lead may be rolled, but if one per cent. of tin is present, the zinc cracks at the edges during the rolling. F. Novak found that zinc is rendered less brittle if it contains 0.25 per cent. of cadmium, and more brittle if it contains over 0.5 per cent. of cadmium. According to C. Künzel, zinc with 0.2 to 0.3 per cent. of chlorine cannot be rolled. According to E. Probst and A. van de Casteele (1913), if the amount of lead in the zinc exceeds 1.25 per cent. the malleability is reduced, the limit with cadmium is 0.25 per cent.; while if over 0.02 per cent. of tin, arsenic, and antimony is present, the zinc is hardened, and this additively.

H. Buff⁷ found the **modulus of elasticity** or **Young's modulus** to be 10,800 to 11,900 kgrms. per sq. mm.; and for cast rods of metal containing 0.1 per cent. each of lead, cadmium, and iron, E. Grüneisen found 12,370 to 13,100 kgrms. per sq. mm., while for impure zinc, with 1.1 per cent. of lead, 0.25 per cent. of copper, and 0.03 per cent. each of iron and cadmium, he found 8910 kgrms. per sq. mm. W. Voigt gave 10,300, and J. Kiewiet 10,477 kgrms. per sq. mm.; G. Wertheim, 8734 kgrms. per sq. mm. at 15° for cast zinc; C. Schäfer gave 4296 kgrms. per sq. mm. at 20° . O. Meyer found the modulus of elasticity of rolled zinc plate 0.044 to 0.051 in. thick, is 12.85×10^6 lbs. per sq. in. with the grain, 14.50×10^6 across the grain, or an average of 13.62×10^6 lbs. per sq. in. For annealed zinc, he obtained 15.95×10^6 lbs. per sq. in. W. Sutherland gave the elastic modulus of zinc between 7670 and 10,550, or an average 9300 kgrms. per sq. mm.; and he estimated that the elastic modulus is 9300 kgrms. per sq. mm. at 15° ; and 1490 kgrms. per sq. mm. at -273° . H. Mark and co-workers studied the mechanism of the stretching of zinc.

For the **torsion modulus**, **rigidity**, or **shear modulus**, J. Kiewiet gave 3820, W. Voigt 3880, and C. Schäfer 1614.4 kgrms. per sq. mm. at 20° . N. Katzenelsohn found 40.0 per cent. change in the torsion modulus between 0° and 100° , and C. Schäfer, 48.37 per cent. change between -186° and 20° . W. Sutherland gave for the ratios of the rigidity at 100° to the value at zero 0.749, and H. Tomlinson, 0.843. For the absolute values of the rigidity between 0° and 20° in grams per sq. cm. Lord Kelvin (W. Thomson) gave 360×10^6 , H. Tomlinson 340×10^6 , and J. Kiewiet 380×10^6 . W. Sutherland's mean is 350×10^6 , or 350×10^6 grms. per sq. cm. at 15° , and at absolute zero 426×10^6 grms. per sq. cm. H. Tomlinson represented the rigidity of zinc at θ° by $nt = n_0(1 - 0.00108\theta - 0.000049\theta^2)$. W. Sutherland gives $n/N = 1 - (\theta/T)^2$, where n denotes the rigidity at θ° ; N , the value at absolute zero; and T , the absolute m.p.

P. Berthier noted that zinc wire 0.002 metre in diameter breaks under a load of 12 kgrms. J. Bauschinger found with tests lasting 6 mins. the average **tensile strength** of rolled zinc is 29,100 lbs. per sq. in., and with tests lasting 81 mins., 23,300 lbs. per sq. in. Hence the rapidity of testing increases the tensile strength of rolled zinc, but with cast zinc the influence of rapidity of loading is slight. A. Martens

found for the ultimate tensile strength, in lbs. per sq. in., and the percentage elongation after rupture :

	19°-27°	80°	120°	150°	170°	200°
Tensile strength . . .	20600	12500	8960	5790	7960	6120
Elongation	12.4	29.4	59.4	101.5	17.1	7.2

The tensile strength is low, and the ductility is a maximum, at about 150°, and hence this is the most favourable temp. for rolling. H. le Chatelier, and P. Ludwik made some observations on the effect of temp. on the breaking stress of zinc. J. Dewar found the breaking stress of cast zinc rods, 0.2 in. diameter, at 15° and -182° to be respectively 25 and 26 lbs. per sq. in. O. Meyer also found the results indicated in Table II, where the data are expressed in lbs. per sq. in. for plates

TABLE II.—TENSILE STRENGTH TESTS OF ROLLED ZINC.

	Rolled.			Annealed.
	With grain.	Across grain.	Average.	Average.
Stress at 1st permanent set . .	1,990	2,420	2,130	2,480
Stress at limit of proportionality of stress to deformation . .	710	1,280	995	1,710
Yield point	11,400	13,640	12,500	11,100
Ultimate tensile strength . . .	30,400	36,800	33,600	17,500
Elongation per cent.	27.2	9.7	18.5	4.6
Reduction of area	43	17	30	5
Modulus of elasticity	12,850,000	14,500,000	13,620,000	15,950,000

0.044 to 0.051 in. thick. Specimens cut across the grain, *i.e.* perpendicular to the direction of rolling, are rather stronger and stiffer than when cut with the grain, *i.e.* parallel to the direction of rolling. The stresses at the elastic limit and yield point are very low, and the yield point is not sharply marked, for the flow of the metal at a high stress goes on for a long time. A ten minutes' immersion of the plates in 5 per cent. nitric acid did not appreciably lessen their ductility or strength. H. F. Moore found that zinc either rolled or cast has no well-defined yield point and its elastic limit is very low. Zinc possesses a relatively high degree of plasticity. The ultimate tensile strength of thin rolled zinc plate (not more than 0.05 in. thick) is about 24,000 lbs. per sq. in. The modulus of elasticity of zinc in tension is about 13×10^6 lbs. per sq. in. The stress per square inch of area sheared developed in punching or shearing rolled zinc plates is about 40 per cent. of the stress developed in punching or shearing mild steel plates. The energy per square inch of area sheared per inch thickness of plate required to punch or shear rolled zinc plates is about 30 per cent. of the energy required to punch or shear mild steel plates. K. E. Bingham measured the tensile strength—maximum stress in tons per sq. in.—and percentage elongation on 2 in. Observations made on the metal at different temp. also showed critical points in the maximum stress at about 190° and 300°; and in the percentage elongation between 160° and 180°, and at about 300°. The tensile strength tests are shown by the continuous curve, Fig. 7; and the percentage elongations by the dotted curve in the same diagram. The critical points appear as breaks in the curve. Experiments were also made on test pieces which had been annealed at different temp. and then quenched, and they too showed critical points in the curve of maximum stress for zinc quenched at 180°, and for zinc quenched between 300° and 310°. The percentage elongations gave critical points at the same temp. E. H. Schulz and co-workers have made observations on this subject. O. Meyer, and F. Novak examined the effect of cadmium and lead on the tensile strength of zinc, and found that 0.25 per cent. raises, and over 0.5 per cent. depresses, the tensile strength of zinc. 1.5 per cent. of lead and arsenic, antimony, and tin

make zinc brittle. E. Grüneisen's and A. Mallock's values for **Poisson's ratio** for zinc are 0.2 to 0.3, i.e. the ratio of the transverse contraction to the longitudinal extension under tensile stress. B. MacNutt and A. Concilio discussed the noises which occur when zinc is stressed above certain loads.

T. W. Richards and co-workers found the average **compressibility**, that is, the fractional change of vol. caused by one megabar press., between 100 and 500 megabars,

FIG. 7.—The Tensile Strength and Elongation of Zinc at Different Temperatures.

to be 1.5×10^{-6} per unit vol. per megabar, or 13.70×10^{-8} per at. vol. per megabar. W. Voigt gave 0.9 to 1.5×10^{-6} for the compressibility of zinc. S. Lussana found that a change of temp. had but a small effect on the coeff. of compressibility which was 2.70×10^{-6} at 9° ; 2.77×10^{-6} at 105° ; 2.81×10^{-6} at 156° ; and 2.83×10^{-6} at 170° . The vol. of zinc at 0° is estimated to change 0.0200 with a change of press. from 0 to 12,000 kgrms. per sq. cm. L. H. Adams, E. D. Williamson and J. Johnston gave 1.74×10^{-6} per megabar for the compressibility of zinc at zero press. and 1.43×10^{-6} at 10,000 megabars press. They represented the change in vol., δv per c.c. produced when the press. changes from p_0 to p , by $\delta v = 0.20 \times 10^{-4} + 1.677 \times 10^{-6}(p - p_0) + 1.52(p - p_0)^2$. What N. S. Kurnakoff and S. F. Schemtschuschny call the **plasticity**, i.e. the press. required to produce a flow of the metal through a given opening at ordinary temp. is 75 kgrms. per sq. mm. N. Werigin, S. Lewkojeff, and G. Tammann also measured the velocity of flow by pressing warm zinc and other metals through an opening. W. E. Dalby studied the plastic extension of zinc. When zinc is compressed by 300 atm., C. J. Burton and W. Marshall found a rise of temp. of 0.062° ; and when zinc is suddenly subjected to 388 atm. press., the observed rise is 0.00016° per atm. increase of press. E. Jänecke made some press. measurements on zinc, and concluded that a transformation occurs between 104° and 120° . The same method gave far too low a point for the m.p. of tin, so that these observations are not suitable for measuring the transformation points of a metal.

P. Berthier's value⁸ for the **coefficient of linear expansion** of zinc between 0° and 100° is 0.000029412; H. Fizeau's value at 40° is 0.00002918, and at 50° , 0.00002908; and A. Schulze's value is 0.0000364 between 20° and 100° . A. Matthiessen's value between 0° and 100° is 0.00002976, and he found unit vol. at 0° becomes at θ° , $1 + 0.00008222\theta + 0.000000700\theta^2$. C. Schäfer's value for the coeff. of expansion is 0.00002905, and W. Voigt gave 0.0000251. N. E. Dorsey found 0.00001910 at -170° , and 0.000002970 at 10° ; E. Grüneisen obtained 0.041006 between -183° and 13° ; and 0.041711 between 19° and 100° . H. Kopp and A. Matthiessen found 0.000089 per degree for the cubical expansion between 0° and 100° . C. B. Comstock found variable results for the expansion of zinc at the same temp. E. Heinemann found that when a zinc rod has been heated for a long time,

it does not return to its original size on cooling. F. C. Calvert and R. Johnson measured the thermal expansion of zinc; they also found that if the **thermal conductivity** of silver is 100, the conductivity of a vertically cast zinc rod is 62·8; of a horizontally cast rod, 60·8; and of rolled zinc, 64·1. G. Wiedemann,⁹ however, found that if the thermal conductivity of silver is 100, that of zinc is 19. F. A. Schulze stated that the conductivities of zinc, cadmium, lead, and tin are of the same order. F. E. Neumann gave the conductivity of tin as 362 when that of copper is 130·6. G. Kirchhoff and G. Hansemann found at 15°, the absolute value of the conductivity of zinc is 0·2545 cal. per cm. per sq. cm. per sec. per degree. H. F. Weber obtained the high value 0·3056; A. Berget, 0·303 between 0° and 30°; and L. Holborn and W. Wien, 0·292. W. Jäger and H. Diesselhorst found 0·2653 at 18°, and 0·2619 at 100°; and C. H. Lees gave 0·280 at -170°, and 0·268 at 18°. G. Glage obtained 0·274 for the absolute thermal conductivity at 50°, and 0·412 for the temp. conductivity, *i.e.* λ/Ds , where λ represents the thermal conductivity, D the density, and s , the sp. ht. W. Jäger and H. Diesselhorst gave 0·4066 for the temp. conductivity at 18° and 0·3914 at 100°, with the temp. coeff. of -0·45 per cent. S. Konno found the thermal conductivity of solid zinc fell from 0·263 at 18° to 0·220 at the m.p.; and on melting the conductivity of the liquid fell to 0·140 at 400°, and to 0·137 at 578°, as illustrated in Fig. 8. P. W. Bridgman found the thermal conductivity of zinc increases linearly with press.

H. Kopp¹⁰ found the **specific heat** of zinc to be 0·0932 between 19° and 47°; P. L. Dulong and A. T. Petit, 0·0927 between 0° and 100°; H. V. Regnault,

FIG. 8.—Thermal Conductivity of Liquid and Solid Zinc.

0·0956 between 0° and 20°; L. Schütz, 0·0963 between 0° and 100°; A. Schüler and W. Wartha, 0·09393; H. Tomlinson, 0·0983; W. Gaede, 0·09356 between 0° and 100°; A. Naccari, 0·0951 at 100°; G. W. A. Kahlbaum, K. Roth, and P. Siedler, 0·0939 for distilled zinc, and 0·0940 for the same zinc which had been compressed at 10,000 atm.; U. J. J. le Verrier, 0·096 between 0° and 110°, and a very variable result, approximately 0·105, between 110° and 300°; and 0·122 between 300° and 400°, and it increases rapidly over 400°. P. Schübel gave 0·0934 at 100°; 0·09644 at 200°; 0·0976 at 300°; and 0·09924 at 396°. E. Bède represented his observations at θ° by $0·0865 + 0·000064\theta$; and A. Naccari, by $0·0907 + 0·0000444\theta$. F. Glaser obtained for highly purified solid zinc at 374°, 0·099925, and at 430° when melted, 0·175992; for zinc with 1·29 per cent. of lead, and 0·60 per cent. of iron, the sp. ht. at 281·5° was 0·099566, and at 488°, 0·18113. U. Behn found the sp. ht. at -186° to be 0·0727; and H. E. Schmitz found 0·0836 for purified zinc at -185°, and 0·0931 at 60°; and respectively 0·083 and 0·091 for the less pure metal. For the sp. ht., and for the at. ht., C_p , E. H. and E. Griffiths found the following data above -127·5°, and F. Pollitzer the numbers below that temp.:

	-206°	-179°	-127·5°	-61·9°	0·1°	21·6°	50·6°	97·5°	123·5°
Sp. ht. . .	0·0523	0·0696	0·08421	0·08898	0·09176	0·09265	0·09412	0·09521	0·09570
At. ht. . .	3·42	4·55	5·50	5·82	6·00	6·06	6·15	6·22	6·26

J. Dewar found 0·0384 for the sp. ht. of zinc at the temp. of liquid air, and the corresponding at. ht. 2·52. J. W. Richards represented the sp. ht. of zinc at θ° between 0° and 400° by $0·0906 + 0·00044\theta$; and he estimated that the sp. ht. of the vapour is 0·325 Cal. per cub. metre, or 0·076 Cal. per kgrm. I. Itaka found the sp. ht. of zinc undergoes a discontinuous change during melting, being, at the m.p., 0·110 for the solid, and 0·121 for the liquid; the corresponding at. ht. are 7·20 and 7·91. As indicated above, P. N. Laschtschenko claimed to have obtained a critical point between 340° and 350° in his calorimetric observations on zinc. K. E. Bingham

found no critical points on the **heating curves** of zinc between 25° and 390°. R. C. Tolman gave 39.7 for the **entropy** of zinc at 25°; G. N. Lewis and co-workers obtained 38.17 (gas), and 9.83 (solid).

An early observation of J. Black¹¹ gave 260° for the **melting point** of zinc; L. B. G. de Morveau, 374°; J. F. Daniell, 412°; and G. G. Person, 433.3° and 415.3° respectively with mercury and air thermometers. Among the later observers, H. L. Callendar and E. H. Griffiths gave 417.57°; G. W. A. Kahlbaum gave 424°; and F. Wüst and co-workers, 419°. The majority of modern observers—L. Holborn and A. L. Day, G. Hindrichs, L. Donsky, E. H. Griffiths, J. Petrenko, A. von Vegesack, K. Lewkonja, A. C. Egerton, V. Meyer, H. L. Callendar, C. Schäfer, etc.—have given numbers very close to 419.4°, which K. Scheel, L. I. Dana and P. D. Foote, and W. Guertler and M. Pirani consider may be taken as the best representative value. C. T. Heycock and F. H. Neville found the f.p. is depressed by cadmium, aluminium, tin, and bismuth; while it is raised by copper, silver, and gold. C. Margot found molten zinc sticks to glass. A. O. Ashman recommended zinc, f.p. 419°, as a fixed point in the calibration of pyrometers because the f.p. on the cooling curve is very sharp; there is no undercooling; the metal is very little oxidized at this temp., and the oxide is not soluble in the metal and therefore has no influence on the f.p. F. Glaser gave 29.86 Cals. for the latent **heat of fusion**; D. Mazzotto, 28.1; and G. G. Person, 29.13 Cals. per kgrm., or 1.8 Cals. per gram-atom. V. Czepinsky gave 1.93 Cals. per gram-atom. C. T. Heycock and F. H. Neville gave 1.82 Cals. per gram-atom. A. C. Egerton, U. J. J. le Verrier, and A. Ledebur have made observations on this subject.

E. Tiede and E. Birnbrauer¹² found that when zinc is heated in the vacuum furnace, it forms a crystalline sublimate on a hot surface, and a mirror on a cold surface. C. Barus, and O. Ruff and B. Bergdahl measured the **vapour pressure** of zinc in mm. of mercury and the temp. of distillation under two atm. press., and the former found:

	675°	699°	732°	758°	792°	833°	873°	900°	933°
Vap. press.	26	35	65	101	158	264	425	557	768

J. W. Richards also calculated the following values for the vap. press. of zinc in mm. of mercury:

	248°	363°	477°	592°	706°	821°	930°	1298°	1928°
Vap. press.	0.0002	0.026	0.779	9.23	58.82	242	760	10488	123120

The vap. press. curves for zinc, cadmium, and mercury are indicated in Fig. 9. A. C. Egerton has made observations on the vap. press. p , of zinc, and at the absolute temp. T° he found

$p = 1.17 \times 10^{14} T^{-1} e^{-3.28 \times 10^4 / RT}$ dynes per sq. cm., or, $\log p = 10.9443 - 0.5 \log T - 7176 T^{-1}$ in mm. The slope of the vap. press. curve of zinc at the m.p. is 4.41×10^{-3} ; the vap. press. formula of J. A. M. van Liempt is $p = -684/T + 5.70$ atm., where T is the absolute temp.; the sublimation curve is $\log p = -7266/T + 6.28$. C. Barus' formula is $\log p = 20.98 - 8619T^{-1} - 3.868 \log T$; and H. Braune's $\log p = 6655T^{-1} - 1.147 \log T + 12.046$. H. C. Greenwood also made some measurements of the vap. press. of zinc; the latter found 6.3×760 mm. at 1393°, 11.7×760 mm. at 1503°; 21.5×760 mm. at 1553°; and 53×760 mm. at 1783°.

F. A. Heneglein gave $\log p = -4.6222 \times (1179.6T^{-1})^{1.1092}$ atm. J. A. M. van Liempt

FIG. 9.—Vapour Pressure Curves of Zinc, Cadmium, and Mercury.

gave 26.10 for **Trouton's constant**; H. Braune, 7.24 for the **chemical constant**. C. Zenghelis inferred that zinc evaporates at ordinary temp. in a dry space because it formed a gold-coloured alloy with silver foil placed a short distance away; W. Spring also inferred that zinc is volatile at 300° because it then forms an alloy with lead; and it alloys with copper at 380°; C. J. Hansen, E. Demarçay, A. Schuller, and F. Krafft said that zinc evaporates in vacuo at 184°, and it sublimes rapidly in vacuo when exposed to green cathode rays. J. Stark and S. Kinoshita made zinc-vapour lamps analogous to mercury-vapour lamps; and J. Stark and R. Küch said that the glow is easily started when the zinc lamp is warmed to a rather higher temp. than is needed for cadmium. C. J. Hansen found the **boiling point** of zinc is 920° at 760 mm. press., and 550° in vacuo. F. Krafft also found the vap. press. of zinc is one atm. at 920°—K. Friedrich and A. Leroux gave 902°; W. R. Mott, 930°; J. Violle, 929.6° at 760 mm.; O. Ruff and B. Bergdahl, 930°; J. A. M. van Liempt, 931°; E. Becquerel, 930°; C. Barus, 905° to 929°; H. von Wartenberg, 918°; W. McA. Johnson gave 918° to 922°, or 919° at 743 mm. press.; and A. C. Egerton, 918°; if p mm. denotes a barometric press. near to 760 mm., D. Berthelot found the b.p. of zinc to be $918^\circ + \frac{1}{8}(p - 760)^\circ$. F. Krafft and P. Lehmann gave for the b.p. of zinc the following temp. referred to mm. of mercury; and H. C. Greenwood the temp. referred to atm.:

Pressure in mm.						Press. in atm.			
Press.	60	85	100	120	135	6.3	11.7	21.5	53
B.p.	545°	552°	553°	554°	650°	1120°	1230°	1280	1510°

C. Barus estimates the b.p. of zinc rises about 1.5° for every 10 mm. increase of press. above 760 mm. H. St. C. Deville said that zinc boils at 929° to 954° in dry air; at 916° to 925° in hydrogen; and at 1067° to 1079° in carbon dioxide. C. Féry distilled all the zinc from brass by heating an alloy containing 37 per cent. of zinc in an electric arc-furnace for two minutes. A. R. Haslam also made experiments on the fractional distillation of zinc from copper; and T. Turner and co-workers, on the effect of inert gases at different press. on the speed of volatilization. According to F. Braun, if brass be disintegrated at its m.p., the zinc distils from the particles. W. Sutherland calculated values of $dp/d\theta$ from C. Barus' vap. press. measurements and showed that the latent **heat of vaporization** of liquid zinc is 28.3 Cals. per gram-atom; W. McA. Johnson obtained 451 cals. per gram, and J. W. Richards, 426 cals.—approximately 33.7 Cals. per gram-atom. J. Traube, A. Wehnelt and C. Musceleanu, A. C. Egerton, and E. van Aubel also calculated values for this constant—the latter gave 365.8 cals. per gram; and J. A. M. van Liempt gave 31,430 cals. at the b.p. For the heat of sublimation, C. C. Person gave 1840 cals. E. Beckmann and O. Liesche measured the raising of the b.p. of zinc amalgams and found the results agreed with the monatomic condition of zinc at these temp. K. Bennewitz studied the **rate of evaporation** of molten zinc. W. G. Duffield gave 3.9×10^4 cms. per sec. for the velocity of the mols. projected from boiling zinc.

M. Knudsen found that the condensation of the vapour on a clean glass or mica surface has a critical temp. between -140° and -130° below which all the vapour is retained and above which an appreciable fraction is repelled. R. W. Wood, and A. C. Egerton have also discussed the condensation of vapours on glass surfaces. As previously indicated, by cooling zinc vapour it can be condensed to a liquid; the more the vapour is diluted with air, the more difficult is this vapour to condense. When the temp. of the vapour falls below the m.p. of zinc, it solidifies in the form of a powder—**zinc fume** or **blue powder**. L. V. T. Lynen has stated that zinc vapour produced in the ordinary distillation process condenses between 415° and 550°; and W. Hempel, that the zinc vapour produced in the reduction of zinc oxide in the blast furnace, condenses below 470°. According to J. W. Richards, the dew-point of the vapour is the temp. at which it begins to deposit zinc, so that if the gas from the retort contains 57 per cent. of carbon monoxide and 43 per cent. of zinc vapour, the latter supports 760 \times 0.43 or 327 mm. press., and from the table of vap. press.

of zinc, the mixture becomes sat. with zinc vapour at 847° , i.e. 83° below the normal b.p. of the metal. Similarly, a gas containing 12.8 per cent. of zinc vapour, 38.4 per cent. of carbon monoxide, and 48.8 per cent. of nitrogen, has the zinc vapour under a partial press. of 760×0.128 or 97 mm. The dew-point for that press., from the table of vap. press., is 745° or 185° below the normal b.p. of the metal. F. Krafft found drops of zinc exhibited Leidenfrost's phenomenon.

P. Drude¹³ found zinc to be the most opaque of metals for sodium light. F. de la Provostaye and P. Desains found that zinc reflects 68 per cent. of normally incident lamp light, and P. Drude, 77 per cent. of red light. W. Meier estimated the following values for the **refractive index**, μ ; the **index of absorption**, k , such that the amplitude of a wave after travelling one wave-length, λ , measured in the metal, is reduced in the ratio $1 : e^{-2\pi k}$, or, for a distance, S , in the ratio $1 : e^{-2\pi S k / \lambda}$; and the percentage **reflecting power**, R , of zinc, when λ is less than unity; the values of R , when λ is greater than unity, are by W. W. Coblentz:

λ	.	.	0.257	0.441	0.589	0.668	1.0	2.0	4.0	7.0	12.0
μ	.	.	0.55	0.93	1.93	2.62	—	—	—	—	—
k	.	.	0.61	3.19	4.66	5.08	—	—	—	—	—
R	.	.	20	73	74	73	80	92	97	98	99

J. C. Jamin, L. Natanson, A. Beer, G. Quincke, S. Haughton, W. W. Coblentz, and W. Voigt have also made observations on the refractive index or on the reflecting power of zinc. For plane polarized light reflected from a polished surface with the **principal incidence**, ϕ , $80^{\circ} 35'$, the change is 90° , and if the plane polarized incident beam has a certain azimuth, **angle of principal azimuth**, ψ , $34^{\circ} 35'$, circular polarized light results. J. H. Gladstone's value for the **refraction equivalent** of zinc is 9.8; W. J. Pope's, 12.40 for the *D*-ray. J. Kanonnikoff, and A. Ghira have investigated this subject. C. Cuthbertson and E. P. Metcalfe found the refractivity of zinc vapour, $(\mu-1) \times 10^6$, is 2070 for $\lambda=518.3\mu\mu$; 2150 for $\lambda=546.0\mu\mu$; 2060 for $\lambda=589.3\mu\mu$; and 1960 for $\lambda=656.3\mu\mu$. M. Faraday found that a film of zinc depolarized a ray of **polarized light** giving a red image which was reduced to a minimum by the rotation of the analyzer, and then converted to a blue image. S. Procopiu found that the birefringence is positive, but with finely divided cadmium suspended in toluene it is negative; and similarly with benzene, etc.

J. A. Wilkinson¹⁴ observed no fluorescence during the action of chlorine, bromine, or iodine on zinc, but there is a bright green fluorescence when oxygen or sodium peroxide acts on the metal. The fluorescence is bluish-white with ammonium persulphate; greenish-white with zinc and sulphuric acid in electrolysis; and with zinc sulphate in the cathode rays there is a bluish-white fluorescence—E. Wiedemann and G. C. Schmidt say the latter is white. J. A. Crowther found the ratio of the coefficient of absorption of zinc, μ , for the β -rays to the density of the metal, is $\mu/D=6.95$. H. R. von Trautenberg found the range of the α -rays in zinc to be 22.8×10^{-4} cms. G. A. Sutherland and L. H. Clark measured the range of the β -rays in zinc. W. J. Russell and F. Soddy gave for the coeff. of absorption, μ , for the γ -rays of radium 0.228, or $\mu/D=3.93$; for the uranium γ -rays, $\mu=0.329$; for thorium-*D* γ -rays, $\mu=1.233$; for mesothorium γ -rays, $\mu=0.53$. The absorption of rays emitted by radioactive substances has also been investigated by K. W. F. Kohlrausch, A. Wood, V. J. Laine, J. Meyer, W. Schmidt, E. Riecke, H. A. Bumstead, etc. The emission of radiations by zinc and its alloys when heated in air to 100° and cooled have been studied by R. Blondlot. The secondary radiations emitted by zinc under the influence of **X-rays** have been studied by C. G. Barkla and co-workers, P. D. Innes, J. Borgmann, N. R. Campbell, J. C. McLennan, E. Hjalmar, R. Whiddington, K. Siegl, C. Fuchtbauer, D. Hurmuzescu, etc. J. A. Becker studied the action of a magnetic field on the absorption of X-rays by zinc. The high frequency X-ray spectrum has been studied by H. G. J. Moseley, D. Coster, V. Dolejssek, E. Friman, etc. R. Blondlot found a phosphorescent screen of calcium sulphide glows more brightly when a piece of silver, copper, zinc, lead, or moist cardboard is placed near to it, but gold, platinum, glass, and dry cardboard are

inactive. E. A. Bichat found copper, zinc, and glass absorb **n-rays**, while platinum, silver, or aluminium do not. J. Stark and G. von Wendt studied the series spectra obtained by the action of the **canal rays**.

According to W. J. Russell,¹⁵ polished zinc exerts a strong **photographic effect** on a photographic plate. B. Lengyel found the action more intense in moist carbon dioxide; it is feeble in air containing moist carbon dioxide, and in dry air free from carbon dioxide no action was observed in 16 hrs. G. W. A. Kahlbaum found the action to be dependent on the temp. as well as on the moisture; the radiations are said to pass through glass, and to be influenced by gravitation. B. L. Vanzetti found zinc to be less active than cadmium, but more active than aluminium, lead, or iron. R. Colson attributed the action to a slight vaporization of zinc at ordinary temp. H. Muraoka and M. Kasuya's experiments also agree with the assumption that the reducing action on the photographic plate is produced by vapour. F. Streintz and co-workers, A. Bryojawlensky, N. Piltschikoff, J. Blaas and P. Czermak, E. Rumpf, etc., have studied the action of zinc on potassium iodide, and on photographic plates. A. Nodon found that a sheet of zinc is opaque to the penetrating solar photogenic radiations, but a sheet of metal with a high valency is transparent.

W. Ramsay and J. F. Spencer¹⁶ arrange the metals in the order Al, Mg, Zn, Sn, Cd, Pb, Bi, Au, . . . with respect to their **photoelectric effect** in air; K. Herrmann gives the order Al, Zn, Mg, Sn, Bi, Cd, Pb, Cu, . . . E. Ladenburg gave the order Cu, brass, Zn, Bi, . . . when tested in vacuo, and R. A. Millikan and G. Winchester gave Cu, Au, Ni, brass, Ag, Fe, Al, Mg, Sb, Zn, Pb. . . . The latter gave 0.197 volt at 26° for the positive potential assumed by the metal in vacuo under the influence of ultra-violet light. W. Hallwachs studied the effect of adsorbed gases. W. Frese found the photo-sensitiveness of zinc is greatly reduced by treatment with water or alcohol. R. Hamer found the limiting frequency for the photoelectric effect to be $\lambda = 3426$ 74.

The **spark spectrum** of zinc was examined by C. Wheatstone¹⁷ in 1835, and H. F. Talbot, in 1836, noted some characteristic lines; A. Masson gave a drawing of the spectrum; and D. Alter, and A. J. Angström made further observations. G. Kirchhoff measured some of the spectral lines of zinc, and compared them with the Fraunhofer lines of the solar spectrum. T. R. Robinson made some inaccurate measurements of the spectral lines of zinc, but numerous accurate measurements have since been made by W. Huggins, R. Thalén, L. de Boisbaudran, E. Mascart, A. Cornu, J. N. Lockyer, G. D. Liveing and J. Dewar, W. N. Hartley and W. E. Adeney, J. S. Ames, H. Kayser and C. Runge, W. F. Meggers and K. Burns, G. A. Hemsalech and A. de Gramont, etc. The more important of the 73 lines in the arc spectrum of zinc, expressed in 10^{-8} cms. units, in air at 15° and 760 mm., are 3036, 3072, and 3345 in the ultra-violet; **4630.06, 4680.138, 4722.164, 4810.535**, and 4912 in the blue; **4925** in the greenish-blue; 6103 and **6362.345** in the orange. The lines numbered in clarendon type are illustrated in Fig. 10. F. Brasack claimed

FIG. 10.—The Spark Spectrum of Zinc.

to be able to detect 0.00000015 mgrm. of zinc by the spark spectrum. W. Schuler found that characteristic lines can be observed in the spark spectrum with 0.00002 mgrm. of zinc chloride; 0.00001 mgrm. of zinc bromide, iodide, nitrate, or sulphate. R. C. Dearle, and F. M. Walters studied the infra-red spectrum of zinc.

The spectra of magnesium, cadmium, and zinc embody a number of **line-series**, as illustrated in Fig. 3, Cap. Magnesium. H. Kayser and C. Runge represent the first two series of triplets in the spectrum of zinc by the formulæ:

FIRST SERIES.

$10^8\lambda^{-1}=42945\cdot32-131641n^{-2}-1236125n^{-1}$
 $10^8\lambda^{-1}=43331\cdot71-131641n^{-2}-1236125n^{-1}$
 $10^8\lambda^{-1}=43521\cdot48-131641n^{-2}-1236125n^{-1}$

SECOND SERIES.

$10^8\lambda^{-1}=42954\cdot59-126919n^{-2}-632850n^{-1}$
 $10^8\lambda^{-1}=43343\cdot65-126919n^{-2}-632850n^{-1}$
 $10^8\lambda^{-1}=43533\cdot32-126919n^{-2}-632850n^{-1}$
